Posterior urethral valves

63

Stephen A Zderic and Douglas A Canning

Background

Hugh Hampton Young initially described posterior urethral valves and proposed the current classification scheme.[1] Dewan and colleagues argued for an alternative to Young's system and proposed the term congenital posterior urethral membrane.[2] Regardless of the classification, it is clear that this anomaly presents with great variability.[3] Posterior urethral valves occur in 1 in 5000 live births, which would mean that some 400–500 new cases occur in the United States every year. Although this might seem to be a small number of cases, one must consider that within this cohort of patients, approximately 150 will develop end-stage renal disease (ESRD) and require either dialysis or transplantation within their first 18 years. Given today's advances in dialysis and transplantation, and life expectancies that will approach 70–80 years, this small number of patients places a substantial financial burden upon the healthcare system. Clearly, anything that can be done to lower the incidence of ESRD in this population will have a substantial societal impact, in addition to a profound effect upon the lifestyle of the boy and his family.

Embryology and classification

In Young's original classification, type 1 posterior urethral valves begin as leaflets that originate at the distal aspect of the verumontanum and then fan out to fuse in the midline just proximal to the external striated sphincter. Type 1 valves are a hypertrophied variant of the inferior urethral crest, which is formed by the insertion of the distal ends of the wolffian ducts into the anterolateral walls of the cloaca.[4] Stephens believes that the remnants of the normal urethral crest are visible as non-obstructing ridges that sweep inwards from the lateral walls of the prostatic urethra and converge in the midline at the verumontanum (Figure 63.1). Cranial to this fusion at the verumontanum, the wolffian ducts and associated ureteral buds are absorbed into the bladder neck and trigone. However, if the wolffian ducts should insert into the anterior wall of the cloaca, these folds would become more prominent with a propensity to fuse in the midline. Depending upon the degree to which this occurs, the valve leaflets will then become obstructive in nature. Type 1 valves account for 90–95% of all cases. Type 2 valves in Young's original classification are not obstructing, and reflect mucosal folds extending from the verumontanum superiorly to the bladder neck.

Type 3 valves represent a circumferential annulus that resembles a stricture. These account for 5–10% of all cases of posterior urethral valves. Their embryologic origin is different and probably arises from a persisting urogenital membrane.[4] The urogenital membrane is the anterior portion of the cloacal membrane that the urorectal septum divides.

The exact embryologic origins of posterior urethral valves remain unclear, and await further study with modern molecular techniques being applied to fetal and neonatal postmortem specimens.[5] Although numerous knockout mice have been described with abnormalities of ureteral budding, none developed posterior urethral valves. Thus far, the only models of posterior urethral valves involve the surgical creation of partial or complete fetal bladder outlet obstruction in several species.

The spectrum and consequences of posterior urethral valves

Mild cases of posterior urethral valves may remain asymptomatic until adolescence or even adulthood. Severe cases usually present in utero with abnormal

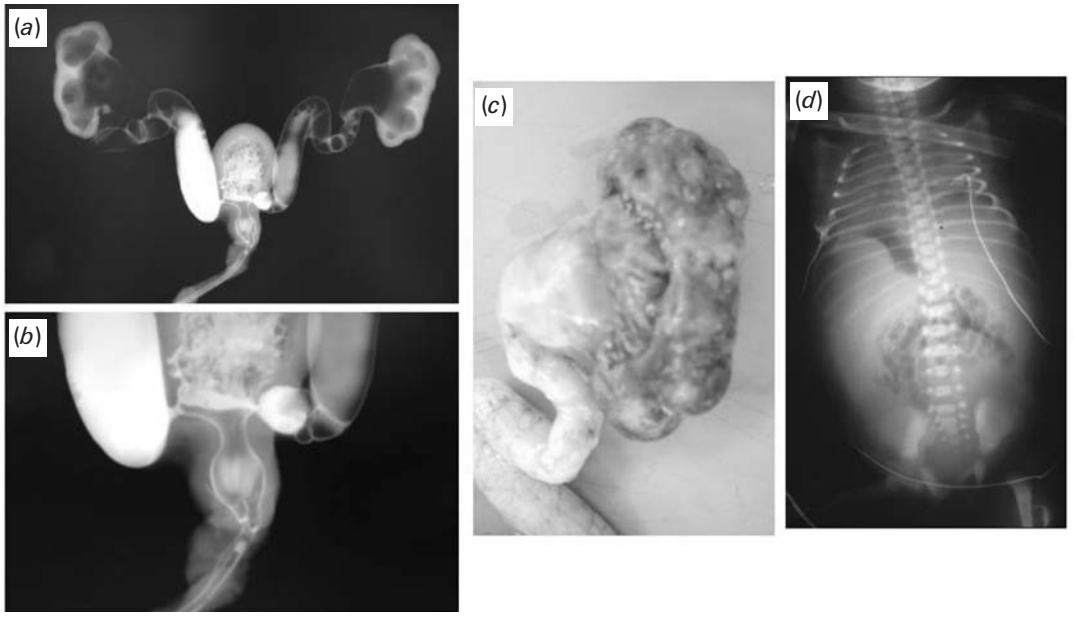

Figure 63.1 The consequences of severe type 1 posterior urethral valves. (*a*) Severe bladder wall thickening was associated with bilateral reflux in this postmortem retrograde study performed ex vivo. (*b*) The hallmark of type 1 valves is the origin of the cusps at the verumontanum, which fan out laterally and fuse in the midline. (*c*) Associated with this is severe cystic dysplasia. (*d*) Because of the oligohydramnios in utero, severe pulmonary hypoplasia developed in the neonatal period and was the cause of death. ((*a–c*) Courtesy of Dale Huff MD and Christopher Austin MD.)

fetal sonography. Alternatively, they may present in the neonatal unit with a palpable bladder and urinary retention. In the most severe cases, as shown in Figure 63.1, the bladder outlet obstruction from the valve results in severe hydroureteronephrosis and cystic dysplasia within the kidney. In these boys, pulmonary hypoplasia may commonly lead to neonatal death. However, the primary pathophysiology begins with the onset of partial bladder outlet obstruction.

Pathophysiology of bladder outlet obstruction

The varied spectrum of outcomes noted in boys born with posterior urethral valves may represent differences among patients in the degree of obstruction, the timing of the obstruction, and underlying genotypic risk factors. To better understand these diverse outcomes, a brief discussion of the pathophysiology of bladder outlet obstruction is important. In a simplified scheme, partial bladder outlet obstruction begins with the onset of bladder wall hypertrophy that enables the bladder to adapt to its new workload. During this compensated phase, the bladder is capable of generating a high voiding pressure, and may empty nearly completely. Over time, however, these compensatory mechanisms fail to keep pace with the demands, and the volume of the postvoid residuals begins to increase. The rising storage pressures within the bladder are transmitted to the renal pelvis, calices, and ultimately to the glomerulus, resulting in renal damage. The pathophysiology of this process is complex and incompletely understood. It is, however, clinically important, given that long-term bladder dysfunction may plague these patients in their daily lives despite successful valve ablation.

Effects on bladder function

The impact of partial outlet obstruction on subsequent bladder function has been the subject of ample investigation. A review of the literature reveals a myriad of studies using human tissues taken at the time of surgery as well as a large number of fetal and adult animal models. In this brief overview, we hope to summarize the steps that lead to bladder dysfunction in the face of partial outlet obstruction. There is evidence to support the following tenets: the presence of partial outlet obstruction leads to an increase in smooth muscle size (hypertrophy) and an increase in the deposition of extracellular matrix. The pathophysiologic changes in the bladder wall lead to an alteration in blood flow to the detrusor that ultimately

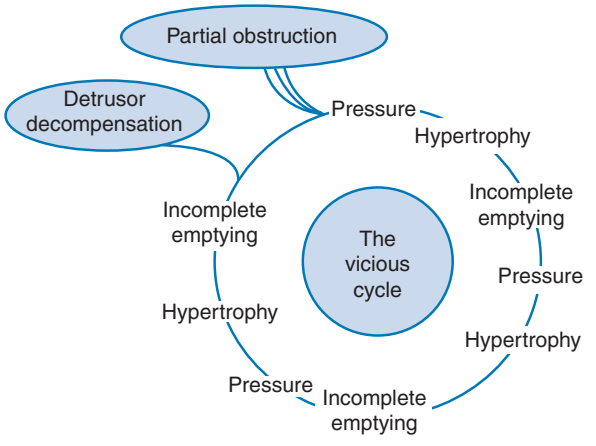

Figure 63.2 Mitchell's schematic concept of how partial outlet obstruction affects the bladder cycle and, over time, alters the bladder.

results in ischemia, a shift to anaerobic metabolism, and damage to the nerves within the bladder wall.

If one characterizes disorders of voiding into failures of bladder storage or bladder emptying, one can understand how partial bladder outlet obstruction interrupts this cycle. Mitchell summarized this concept nicely in a diagram (Figure 63.2) which illustrates that mild hypertrophy follows outlet obstruction; this results in higher voiding pressures that initially preserve near-complete bladder emptying. However, as this filling and emptying cycle repeats, further remodeling of the bladder wall occurs, and gradually the postvoid residual begins to increase. In the developing fetus with posterior urethral valves, the rise in urine output that accompanies normal growth and development further stresses this system. Ultimately, the bladder's ability to adapt cannot keep pace with the functional demands, and the detrusor decompensates. In this setting, the bladder continues to produce elevated voiding pressures, but it does so inefficiently, at the expense of an elevated resting pressure before voiding, and a markedly increased postvoid residual.

Researchers have wondered if the bladder has a functional reserve upon which additional demands may be imposed without penalty. Sullivan and Yalla[6] offered evidence in favor of the detrusor functional reserve, which they defined as the peak isometric pressure (measured by balloon occlusion of the outlet) minus the peak voiding pressure. With mild obstruction and a minimal postvoid residual, this number was always in excess of 40. However, as the detrusor reserve dropped, the postvoid residual began to rise. These studies were done in adults and for technical reasons have not been replicated in the fetus; but it is logical to assume that a similar concept would apply in the fetal setting.

Experimental models of fetal partial bladder outlet obstruction have provided some insight into this pathophysiology.[7] Cystometry following partial outlet obstruction in the fetal sheep revealed a spectrum of curves similar to that noted in other models. Kirsch et al[8] noted a remarkable increase in bladder compliance ($\Delta V/\Delta P$) following partial outlet obstruction. The more compliant bladders were associated with upper tract dilatation. Because Kirsch performed these cystometrograms in the operating room, he ligated the ureters, which means that these measures were a true reflection of bladder compliance. These data would suggest that as the bladder underwent decompensation, the upper urinary tract was placed at risk.[9] Using the fetal sheep model of partial outlet obstruction, several groups have described a large distended bladder with poor contractile performance of selected muscle strips in vitro.[10,11] Similar findings were noted in a rabbit model of fetal bladder outlet obstruction by Rohrmann et al,[12,13] who performed in-vitro cystometry and noted an increased bladder capacity with low intravesical pressures. The common theme across all these models was the marked deposition of extracellular matrix elements between the muscle bundles that is very similar to what is described in specimens from patients with posterior urethral valves.[14]

Researchers have tried to answer a list of fundamental questions. First: What are the molecular pathways that account for the less efficient bladder function seen following outlet obstruction? Understanding these steps is critical if one tries to prevent damage to the bladder during the course of gestation using pharmacologic intervention. This approach is important in the fetus because surgical intervention for posterior urethral valves in the fetus has been shown to carry as high as a 50% fetal mortality rate.[15] In order to realize this goal, we need to understand the molecular pathways that lead to the bladder dysfunction in the face of partial outlet obstruction. A simplified scheme of this complex pathophysiology is suggested in Figure 63.3.

Does the bladder respond to the rise in intraluminal pressure or to stretch? Numerous studies suggest that outlet obstruction and progressive stretch applied to the bladder wall are the key factors mediating these molecular changes. Park et al demonstrated this concept in a rat model of complete outlet obstruction in which the upper half of the bladder was constrained

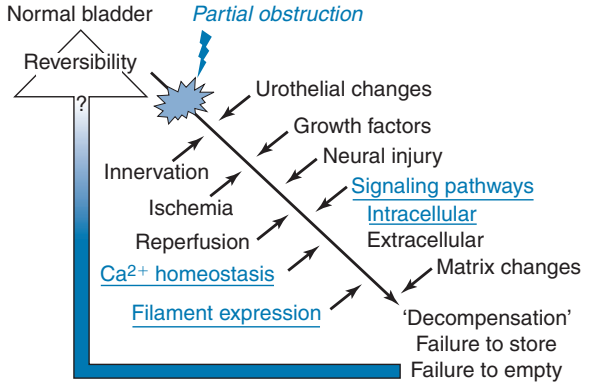

Figure 63.3 A schematic representation of the proposed sequence of events that result in the bladder following partial outlet obstruction. Initial changes take place that allow the bladder to compensate and generate higher pressures with minimal increase in postvoid residual. However, over time, additional changes take place and the postvoid residual begins to rise, reaching the stage termed as decompensated. Although there is experimental evidence to support a role for each of these factors, the exact sequence of these events remains poorly understood. (Concept and figure developed by DJ Bagli, DT Wilcoxon, B Kogan, and SA Zderic).

within a tube that allowed it to 'sense' pressure, but prevented distention.[16] Park et al noted changes in cyclooxygenase-2 (COX-2) expression only in those bladders that stretched and not in those segments in which the restricting collar inhibited stretch. Furthermore, these changes in COX-2 expression were recapitulated in cultured cells subjected to mechanical deformation.[17] With an in-vitro rat whole bladder model subjected to distention, Bagli and coworkers showed an increase in mRNA expression for collagen type I and III as well as an increase in integrin expression.[18] Using human bladder smooth muscle cells subjected to mechanical stretch in vitro, Adam et al showed changes in expression of some 20 genes (out of almost 12 000 analyzed) using microarray technology.[19]

Is partial outlet obstruction associated with bladder wall hypoxia? There is increasing evidence to suggest that with overdistention, the perfusion of the detrusor is diminished. Using a porcine model of partial outlet obstruction, Greenland and Brading demonstrated a marked drop in wall oxygen tension that was more pronounced with voiding.[20] Similar findings have been noted by other groups.[21] Levin and coworkers have observed increases in the expression of hypoxia inducible factor (HIF), a transcription factor activated in the presence of lowered oxygen tension.[22] Azadzoi et al documented alterations in bladder wall perfusion in atherosclerotic rabbits and, even in the absence of outlet obstruction, bladder wall hypoxia was associated with a marked deposition of extracellular matrix.[23] There is growing evidence to suggest that many of the changes induced by hypoxia in this setting are the result of free radical-mediated damage.[24] Some authors suggest that the reperfusion phase is even more damaging than the hypoxic phase,[25] especially to the neural structures within the bladder wall. These in-vitro findings are supported by the diminished response to neural stimulation observed in muscle strips taken from bladder subjected to partial outlet obstruction using the fetal sheep model.[10,11]

Following outlet obstruction, several changes in bladder morphology have been documented. There is an increase in smooth muscle size[25] (i.e. hypertrophy) and there is a prominent deposition of extracellular matrix components within the bladder wall. This has been shown in human fetal specimens,[14] as well as in numerous fetal models of partial outlet obstruction.[8] Experimentally, there is an increase in collagen synthesis in cultured smooth muscle cells subjected to biaxial mechanical strain,[27] and this is mediated at the transcriptional level, as shown by increased mRNA expression.[28] Changes have also been described in the complex regulatory system that breaks down collagen. The matrix metalloproteinase enzymes are able to break down the extracellular matrix and the tissue inhibitors of the matrix metalloproteinases (TIMPs) may in turn regulate them as a feedback mechanism. Peters et al has shown TIMP expression to be increased within the bladder wall in a fetal sheep model of partial outlet obstruction, thus providing another mechanism for the dramatic increase in bladder wall fibrosis.[29] The clinical relevance of these observations is that this prominent deposition of extracellular matrix alters both the active and passive properties of the bladder wall.

Effects on the upper ureter, renal pelvis, and kidney

Ultimately, as the bladder fails to adapt to its imposed workload (compensate), a sequence of molecular events result in which the bladder begins to retain larger volumes of urine. Consequently, the resting pressure in the bladder before voiding becomes significantly elevated, and this increased resting pressure is transmitted to the upper urinary tract over prolonged periods. It is clear that elevated voiding pres-

sures by themselves do not cause harm to the upper urinary tract. Sillen et al have documented extremely high voiding pressures in normal male infants or those with reflux and normal renal function.[30] Thus, damage to the upper urinary tract occurs because of elevated intravesical storage pressures over prolonged time intervals. The results of this are manifest in the resulting ureteral dilatation and rise in intrarenal pelvic pressures. As a number of investigations have shown, elevated bladder pressures are transmitted back to the renal pelvis.[31]

Elevated renal pelvic pressures ultimately have a profound effect upon renal morphology and function. A complete review of obstructive nephropathy is beyond the scope of this chapter; however, some basic concepts deserve mention. Obstruction impacts renal concentrating ability, glomerular filtration rate (GFR), and renal morphology. Numerous human and experimental observations support the notion that renal concentrating ability is diminished in the presence of obstruction.[32,33] This effect might occur as a result of damage to the luminal cells within the tubules, as shown in a study in which mechanical deformation of renal epithelial cells in culture was associated with apoptosis.[34] It might also reflect changes in blood flow to the medulla[35] and a subsequent loss of the medullary concentrating gradient.[36,37] Although these changes are probably of lesser significance in the fetal kidney that has poor concentrating ability, they have a profound impact in the older patient with posterior urethral valves who is left with pronounced polyuria and a compensatory polydipsia.[38] These changes also can account for the occasional patient who has a postobstructive diuresis following initial catheter placement in the neonatal intensive care unit (NICU).

Most boys with posterior urethral valves experience a drop in their GFR, although this is variable. Some anatomic variants dampen the pressure transmitted by the upper tracts to the kidney and thereby lessen renal damage. When the full effects of high resting pressures are transmitted to the kidneys, fibrosis has been observed clinically and experimentally,[39] both within the renal pelvis and within the renal parenchyma. The cytokine transforming growth factor-β (TGF-β) is associated with this fibrosis and is also secreted into the urine, providing a biologic marker for the presence of obstruction.[40,41] There is also therapeutic potential in this observation, because, in an experimental study, treatment with antibodies to TGF-β alone or in combination with an angiotensin-converting enzyme (ACE) inhibitor resulted in diminished renal fibrosis.[42,43] The deposition of the fibrosis is not necessarily uniform throughout the kidneys, and this might reflect regional alterations in perfusion.

Genotypes and end-stage renal disease

Researchers have tried to determine if ESRD seen in boys with posterior urethral valves is solely a consequence of the obstructive uropathy or the result of delay in treatment in the fetal period. Harrison suggested that fetal surgical intervention for the infant with posterior urethral valves did not lead to improved renal outcomes, although it was associated with better pulmonary outcomes.[44] However, these interventions were reserved for the most severe cases, and the authors concluded that by the time of intervention, the damage from obstructive uropathy may have become irreversible. An alternative explanation might be that these results defined a genotypically distinct at-risk population. The role of the angiotensin II receptor in ureteral and renal development is well established, and its targeted gene deletion may be associated with ureteral ectopia and associated renal hypoplasia.[45]

Given the central importance of the angiotensin receptor in ureteral budding, branching, and renal development, several investigators have sought to study how the renin–angiotensin system (RAS) is altered in patients with posterior urethral valves. Components of the RAS, where such genetic variability arises, include ACE, angiotensinogen, and the angiotensin receptor. Insertion and/or deletions within a fragment of intron 16 of the *ACE* gene will account for up to 50% of the variability of the serum enzyme activity.

If all cases of ESRD associated with posterior urethral valves were attributable to obstructive uropathy alone, there should be no clustering of genotypes according to clinical outcomes. However, the distribution of the *ACE I* allele which is associated with lower enzymatic activity was much more likely to be seen in children with posterior urethral valves and renal insufficiency than it was in a normal population.[46] Despite this observation, higher peripheral renin activity is observed in patients with posterior urethral valves compared with normal age-matched children.[47] This seeming discrepancy may arise because of the difference between the role of the RAS in development and renal branching, and its response in the postnatal period in the face of renal injury. This type of clinical evidence, coupled with a vast experimental literature, argues in favor of an underlying

genetic component to the ESRD observed in this condition. The literature devoted to understanding these genotypic relationships with the various posterior valve phenotypes will grow in the years to come.

Diagnosis

With the widespread use of screening antenatal sonography, the vast majority of patients with posterior urethral valves are being diagnosed in utero. We initially hoped that this increase in diagnostic ability would lead to fetal intervention and better renal outcomes. Despite the widespread use of sonography, there continues to be a high incidence of long-term renal failure in these patients. This suggests either that by the time current imaging technology detects renal damage it is already irreversible or that the patient may have an at-risk genotype, or some combination of the two. Although the use of in-utero sonography has not eliminated ESRD in boys with valves, there has been a decline in the number of older boys who present with symptoms. Even with the widespread use of prenatal sonography, several series report that up to 10–20% of boys present with symptoms such as urosepsis or urinary incontinence.

Fetal imaging

Screening sonography will usually detect a major obstructive uropathy at 18–19 weeks of gestation, and lead to further study with a higher-resolution ultrasound. The finding of a thick-walled bladder and bilateral hydroureteronephrosis in a male fetus suggests posterior urethral valves. However, ultrasonographers also see these changes in boys with the prune belly syndrome. One study suggests that sonography is accurate in making a diagnosis of posterior urethral valves in 50% of cases.[48] In addition to a determination of how much renal parenchyma is present, a critical factor in assessing the sonogram is the presence or absence of amniotic fluid. Oligohydramnios (Figure 63.4) is an ominous sign of advanced and severe obstruction. In recent years, the role of sonography has been supplemented with the use of fetal magnetic resonance imaging (MRI) in highly selected cases (Figure 63.5).[49] The indications

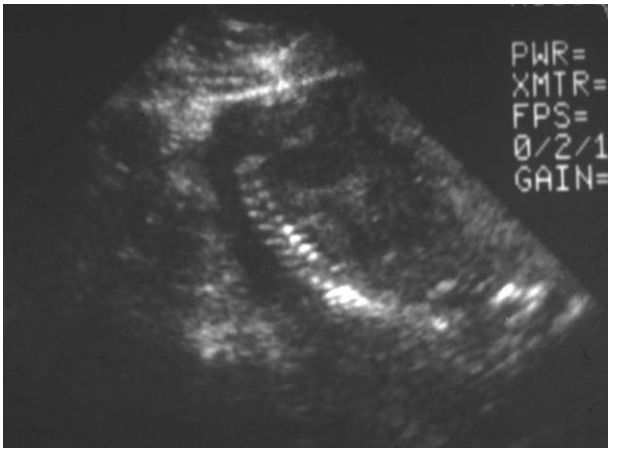

Figure 63.4 A fetal sonogram showing severe oligohydramnios. Note the lack of amniotic fluid between the spine and the uterine wall. Death occurred in the neonatal period from pulmonary hypoplasia.

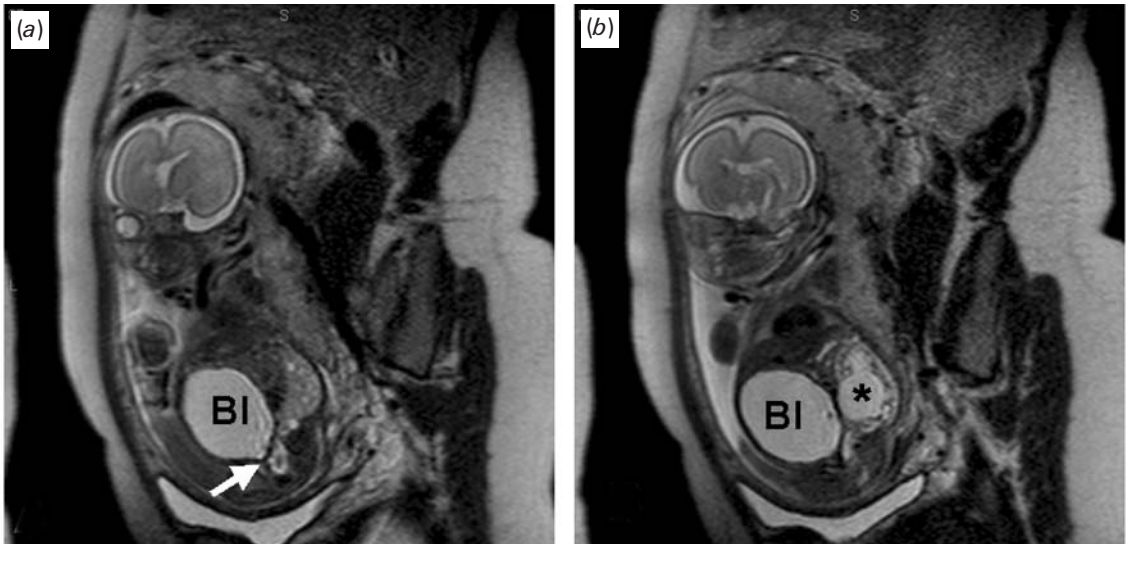

Figure 63.5 A maternal fetal MRI showing amniotic fluid levels and evidence of a dilated bladder (Bl), dilated posterior urethra (arrow) (*a*), and hydroureteronephrosis (*) (*b*).

for fetal MRI in such a setting include bilateral hydroureteronephrosis, bladder wall thickening, and oligohydramnios. In one study of early third trimester gestations, the addition of the fetal MRI altered the initial diagnosis made by sonography in 30% of the cases.[50] Another study revealed MRI to be highly accurate in the assessment of total lung volume (TLV) in patients with genitourinary anomalies after 26 weeks of gestation, but similar predictability was seen using a determination of whether oligohydramnios was present or absent.[51] Further work will clarify the precise benefits this imaging can offer over conventional sonography.

In-utero management – interventional

Harrison's pioneering work in fetal intervention began with extensive experimental work in the fetal sheep model in 1978,[52,53] and the first clinical interventions took place in the early 1980s.[54] In the early years, we hoped that with antenatal diagnosis followed by prompt surgical intervention, the renal prognosis for these patients would improve. Open fetal surgical intervention using either a vesicostomy or ureterostomies were performed and shown to be technically feasible.[44] However, despite technical success in a majority of these cases, the incidence of renal insufficiency remained high.[15] However, intervention improved pulmonary function and the restoration of amniotic volume due to the internal stenting of the aspirated amniotic fluid.[55,56]

It was clear that not all boys with posterior urethral valves benefit from in-utero intervention, because the severity of the obstruction from the valve is so variable. If one performs aggressive intervention in a population skewed towards advanced disease, as shown in Figure 63.1, the results are uniformly disappointing. Most boys have a good prognosis if they complete a normal gestation and have a neonatal valve incision. Attempts to better stratify the at-risk group, in whom fetal intervention for obstructive uropathy would be helpful, led to the development of urinary sampling as a means of predicting which patient might benefit from this approach. The ability to sample urine from the fetal bladder allows for analysis of electrolyte composition and testing for the expression of markers such as β_2-microglobulin. Under ordinary conditions, the fetal urine is hypotonic, which reflects the fetal kidney's poor ability to concentrate the urine. This is because proximal tubular function develops, and active sodium transport results in a hypotonic filtrate. This hypotonic filtrate then passes on through the distal tubules with minimal reabsorption of free water. In contrast, in the older child, this hypotonic filtrate is concentrated by the absorption of free water via the aquaporin channels.[57] Glick et al demonstrated that in the fetus with obstructive uropathy and renal dysplasia, a nearly isotonic urine was observed; this suggests significant problems with proximal tubular function, which mediates sodium reabsorption.[58] In contrast, the fetus with mild renal impairment had low urinary sodium, chloride, and osmolarity. There was initial optimism that urinary aspiration from the bladder with electrolyte and osmolarity analysis might predict long-term renal outcomes. Favorable urinary electrolyte values were deemed as $Na^+ < 100$ mEq/L, $Cl^- < 90$ mEq/L, and an osmolarity < 210 mOsm/L. In the long term, fetal urinary electrolyte analysis still fails to separate those with a favorable renal prognosis from those in whom ESRD develops.[15] The use of additional urinary markers such as β_2-microglobulin has also been investigated,[59] but none offer the perfect predictive test. Freedman et al offered evidence that sequential bladder taps on three successive days might increase the predictive power of this method.[60] Nevertheless, in a recent review, even among those patients with favorable electrolyte patterns, the incidence of ESRD remained increased, at nearly 30%.[61,62] In summary, urinary electrolytes, if unfavorable, can predict the most severe cases of fetal obstructive uropathy seen with dysplasia. However, even patients with a favorable electrolyte pattern may progress to ESRD. The pitfalls of this diagnostic dilemma have been reviewed by Elder,[63] and it remains a fruitful area for further research. Perhaps with the application of proteomics to urine samples collected from patients with known postnatal outcomes, a better marker of irreversible renal injury may be identified.[64]

Neonatal demise in patients with severe posterior urethral valves does not result from ESRD, but rather from pulmonary hypoplasia.[65] The etiology of this appears secondary to the loss of the mechanical distending forces provided by the aspiration of the amniotic fluid.[55,56] This experimental work formed the basis for clinical trials of amniotic fluid replenishment which have resulted in improved neonatal pulmonary function.[66,67] In another smaller review of fetal intervention, Coplen et al reported a high incidence of ESRD in shunted patients, but no evidence of respiratory compromise, which was seen in those patients who were not shunted.[68] To summarize, while we have not realized the hopes of fetal intervention for the prevention of renal failure, we have improved pulmonary

function in the most severe cases. Improved criteria might allow for the promise of fetal intervention to a small and highly selected population of patients with obstructive uropathy.[60] Such efforts should be limited to those centers with expertise in this complex procedure and the antepartum care.

In-utero management – observational

We observe most patients with an in-utero diagnosis of posterior urethral valves with serial sonograms to monitor the degree of urinary tract dilatation and the amount of amniotic fluid. We try to allow these gestations to proceed to term to optimize pulmonary development. Extensive prenatal communication between the obstetrical team and the pediatric urologist is always helpful to establish a clear plan of action for the family and all of the healthcare team. A prenatal visit with the pediatric urologist provides an opportunity to begin the process of parent education. The potential for good renal function and a near-normal lifestyle should be emphasized, as well as the small but real potential for long-term renal sequelae.[69] In severe cases where ESRD is likely, families may opt for termination of pregnancy.[70] The need for antibiotic prophylaxis, a renal bladder ultrasound, and a voiding cystourethrogram (VCUG) must be communicated to the family and referring physicians.

Diagnosis in the older child

Although less common in this era of prenatal sonography, the occasional boy with posterior urethral valves still presents with a history of either urinary tract infection, retention, or incontinence.[2,71–73] Not surprisingly for so diverse a condition, there is a case report of a boy presenting with posterior urethral valves despite a normal prenatal sonogram at 30 weeks' gestation.[74] Boys with a urinary tract infection should have a renal and bladder ultrasound to exclude major underlying structural problems. If the boy has a febrile urinary tract infection or retention, we add a VCUG.

Some older boys with posterior urethral valves have only urinary incontinence. In some cases, it is hard to single out the one boy who has a posterior urethral valve from the many with dysfunctional voiding and wetting from volitional urinary retention. While isolated nocturnal enuresis, or an occasional daytime episode of wetting associated with delays in voiding are not cause for alarm, the boy who presents with regular day- and night-time wetting should trigger a suspicion of bladder outlet obstruction. Under these circumstances, a screening renal bladder ultrasound is required to exclude bladder wall thickening associated with valve leaflets and search for any hydroureter. We also recommend a uroflow study and determination of postvoid residual. The presence of a thick-walled bladder and obstructive uroflow pattern should lead to a VCUG being performed to rule out the presence of posterior urethral valves or a stricture. Once these studies have ruled out any anatomic blockages, treatment of the dysfunctional voiding may proceed. Rarely, boys with posterior urethral valves have been treated for dysfunctional voiding for several years with growing frustration at the lack of progress. Hence, the importance of maintaining a high index of suspicion for this diagnosis in the setting of a clinic filled with incontinent children, the vast majority of whom do not carry this diagnosis.

Postnatal imaging

We prescribe antibiotic prophylaxis in the neonate we suspect of having posterior urethral valves before the postnatal imaging. Imaging begins with a renal and bladder ultrasound, which may be diagnostic. We order a VCUG as soon as possible if the ultrasound has any features that suggest a possibility of posterior urethral valves.

Ultrasound

The presence of a dilated posterior urethra, thickened bladder wall, bilateral hydroureteronephrosis, and cortical thinning in a newborn boy is suggestive of posterior urethral valves (Figure 63.6). In some cases, the hydroureteronephrosis is limited to one side and with an associated cystic- or dysplastic-appearing kidney. This represents the posterior urethral valves, unilateral vesicoureteral reflux, and renal dysplasia (VURD) syndrome[75] in which one renal unit absorbs the brunt of the high pressure and is lost, while the opposite side is spared and undergoes compensatory hypertrophy (Figure 63.7). Ultrasound examination may also detect the presence of urinary ascites. In addition to a thick-walled bladder, the ultrasound may also show an associated diverticulum (see Figure 63.7). Identification of these pressure pop-off mechanisms by sonography is associated with better long-term renal[75,76] and bladder[77] function.

In addition to noting the degree of upper tract dilatation, the intrarenal echogenicity can also serve as a valuable clue to the renal prognosis. Within the normal kidney, there are substantial differences in the echogenicity observed between the renal medulla and

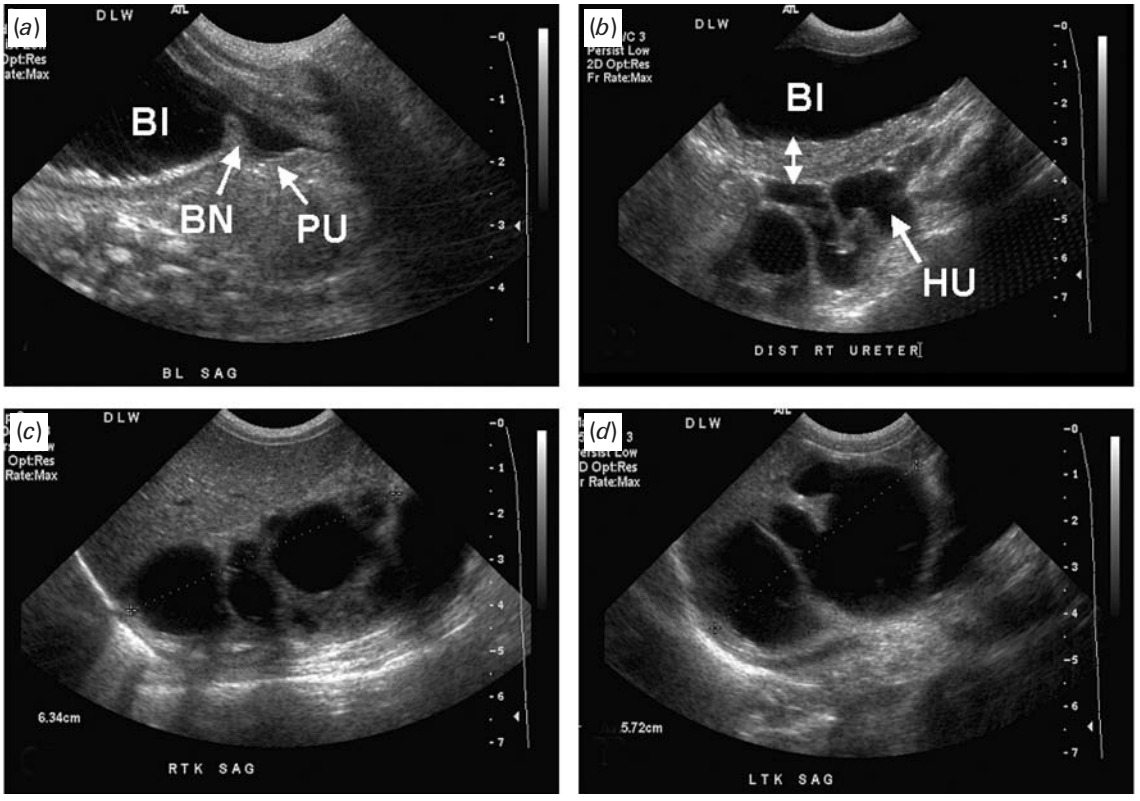

Figure 63.6 This postnatal ultrasound demonstrates the classic findings of severe posterior urethral valves. (*a*) The distended bladder (Bl) can be traced in this sagittal view down to the level of a dilated bladder neck (BN) and dilated posterior urethra (PU). (*b*) The dilated bladder has a very thick wall (arrows) and associated severe hydroureteronephrosis (HU). (*c* and *d*) Both kidneys show severe cortical atrophy.

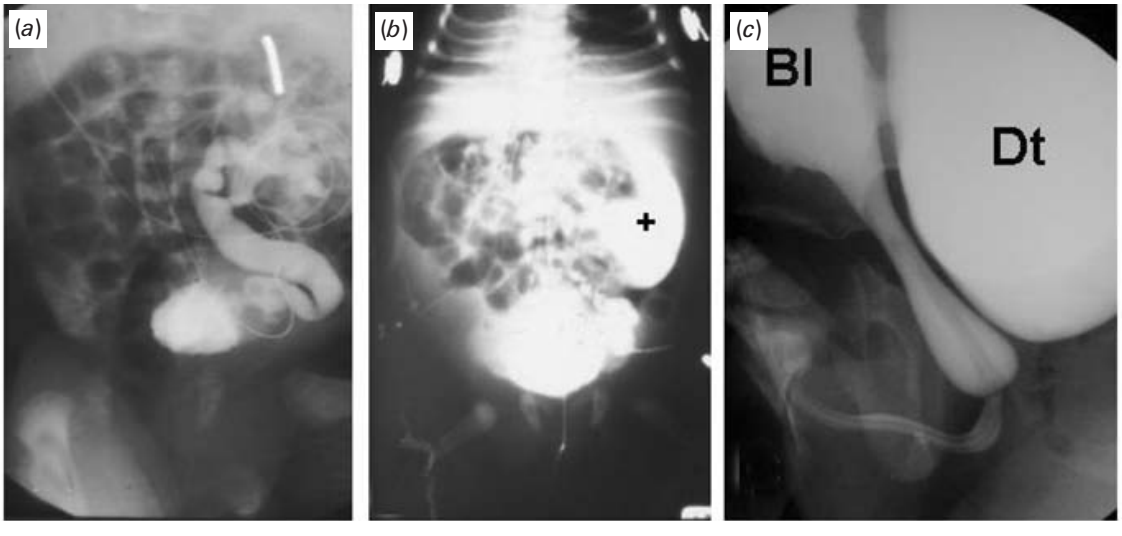

Figure 63.7 Pressure pop-off mechanisms which serve to vent elevated intravesical pressure and preserve renal function have been well described. (*a*) An example of the VURD syndrome in which the left renal unit has high-grade reflux and dysplasia; this spared the right kidney. (*b*) Extravasation into the perinephric space (+) following a forniceal rupture may also occur. (*c*) The large bladder diverticulum spared this patient's renal function (Bl; bladder, Dt; diverticulum).

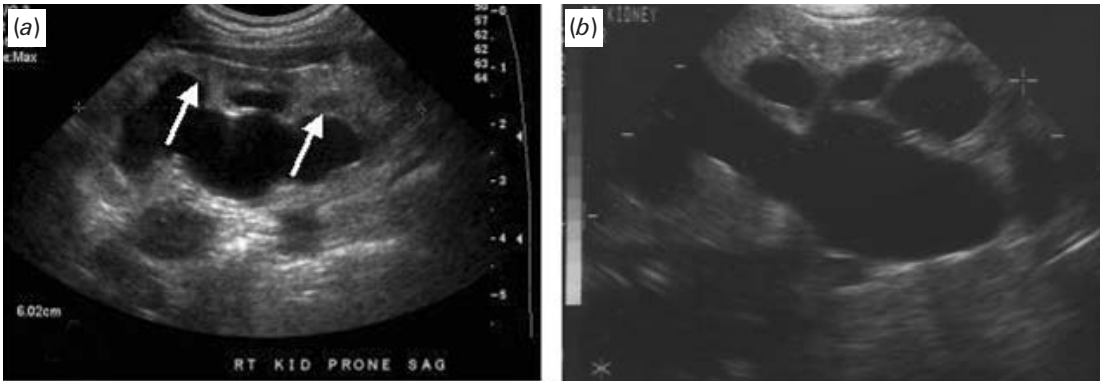

Figure 63.8 (*a*) Differences in renal corticomedullary echo density or differentiation are a favorable prognostic sign. The arrows point to areas within the medullary region that are of distinctly lower density than the surrounding cortical regions; sometimes these areas are mistaken for a fluid-filled calyx. (*b*) In contrast, this renal sonogram shows severe hydronephrosis and a renal parenchyma that is uniformly dense with no corticomedullary differentiation. Fifteen years later, this patient is in renal failure.

cortex (Figure 63.8a). In contrast, with substantial renal damage, there is a loss of this corticomedullary differentiation (see Figure 63.8b), which suggests a more ominous renal prognosis.[78,79]

Voiding cystourethrogram

The VCUG remains the cornerstone of achieving an accurate diagnosis of posterior urethral valves. Sometimes it is difficult to pass an 8 Fr feeding tube (Figure 63.9), which may coil within the dilated prostatic fossa. Using a coudé tip catheter allows for the passage of the catheter over the hypertrophied bladder neck. Once the radiologist fills the bladder and the bladder begins to contract, the catheter is withdrawn to allow fluoroscopic observation of the entire urethra. The characteristic valve cusp appears at the inferior aspect of the dilated prostatic urethra and appears identical to the leaflets seen at the time of cystoscopy (Figure 63.10). Although the diagnosis of valves is not affected by having the catheter in place during micturition (Figure 63.7c), we prefer to have fluoroscopic voiding views free of any interference.

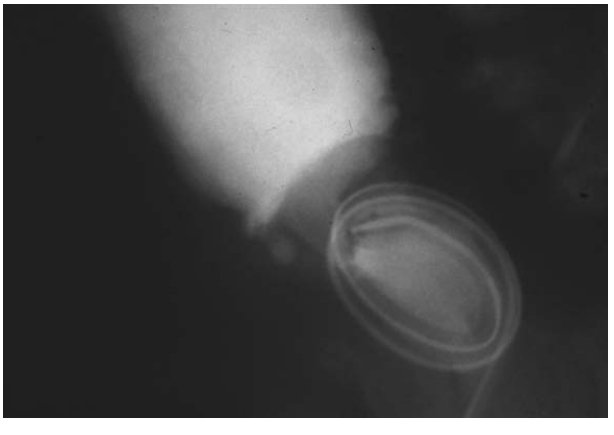

Figure 63.9 The challenge of placing a catheter in a dilated posterior urethra is usually circumvented by using a coudé tip catheter. Occasionally, even a coudé tip catheter will coil in the posterior urethra, and require fluoroscopic placement. This is useful for the older boy with posterior urethral valves who is going to initiate clean intermittent catheterization.

Sometimes it is not clear from the VCUG whether one is seeing a posterior urethral valve, or contraction of the striated external sphincter. It is critical to view each image provided to find a view that demonstrates a relaxed external sphincter. In this case, 'real-time' fluoroscopy is useful. If any doubts remain as to whether or not the narrowing is physiologic or anatomic, we perform cystoscopy to exclude the presence of a valve leaflet. There may be similar concerns on a postoperative VCUG following valve incision. In one illustrative case, initial views showed a narrowing of the distal aspect of the prostatic urethra Figure 63.11b that opened widely on subsequent views (Figure 63.11c).

The VUCG may also reveal the presence of unilateral or bilateral reflux. Unilateral reflux may occur into a dysplastic and non-functioning kidney, and serve as a pressure pop-off mechanism.[75,80] Similarly, a large diverticulum may also serve as a venting mechanism and confer a better renal prognosis. We do not excise these diverticula. We believe that they provide low-pressure storage capacity unless urinary retention or infection intervenes. We have illustrated these concepts with the case study in Figure 63.7.

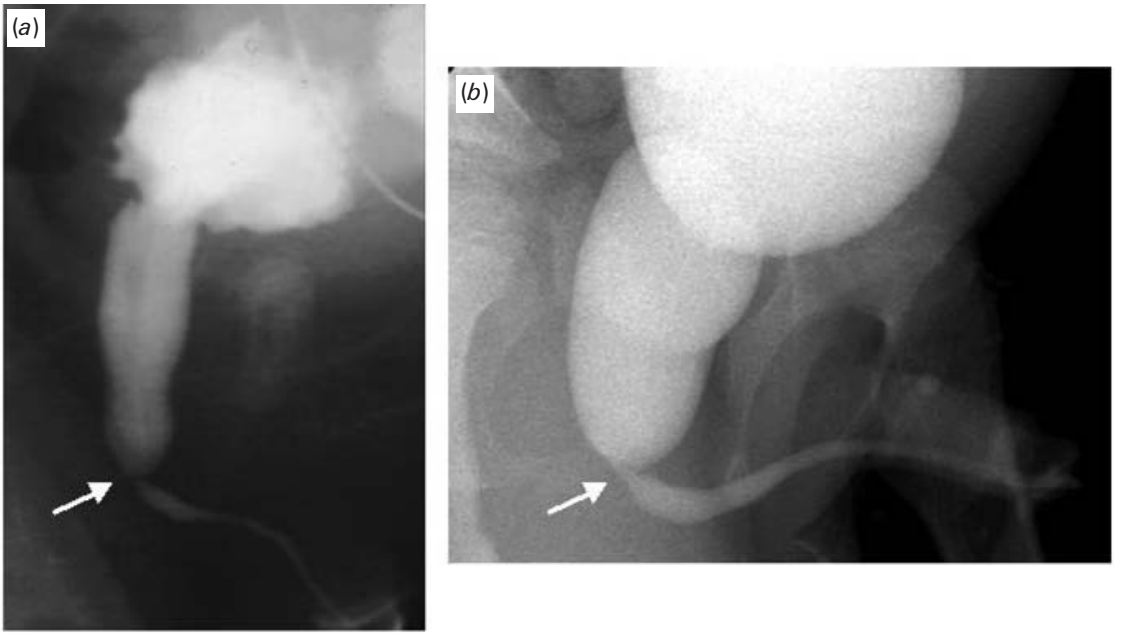

Figure 63.10 (*a* and *b*) The classic valve cusps associated with type 1 posterior urethral valves (arrows) are demonstrated in these two VCUGs.

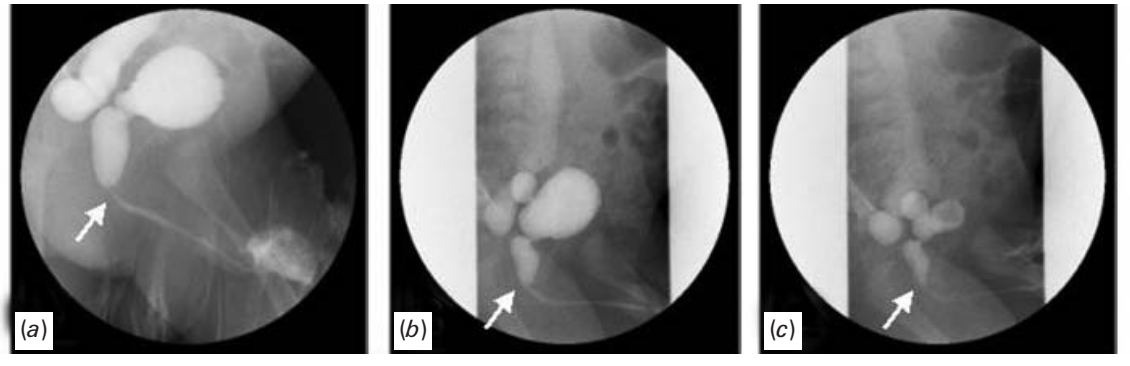

Figure 63.11 (*a*) The classic type 1 posterior valve is shown preoperatively (arrow). (*b*) The postoperative appearance of a VCUG for a patient 3 months following valve resection demonstrates what might appear to be a residual valve leaflet (see arrow). (*c*) However, full review of all the fluoroscopic images reveals this narrowed area opens up when the striated external sphincter is relaxed.

Nuclear medicine

Traditionally, we performed technetium 99m (^{99m}Tc) diethylene triamine penta-acetic acid (DTPA) or mercaptoacetyltriglycine (MAG3) nuclear renal scans to quantify GFR in boys with posterior urethral valves, especially in the presence of the VURD syndrome. If the refluxing kidney was associated with a poor GFR, nephrectomy was the traditional management recommendation. Our presumption in the past was that high-grade reflux into a non-functioning system risked infection. We now believe that this risk is low because:

- most of these boys remain on prophylactic antibiotics long term
- in the United States, circumcision is widely practiced, further lowering the risk of urinary tract infection.

We no longer recommend a routine renal scan unless we suspect secondary ureteral obstruction, and this is rare.

Management options

Initial management in a neonatal intensive care unit

Following delivery, we allow a healthy neonate with good pulmonary function to bond with his mother and

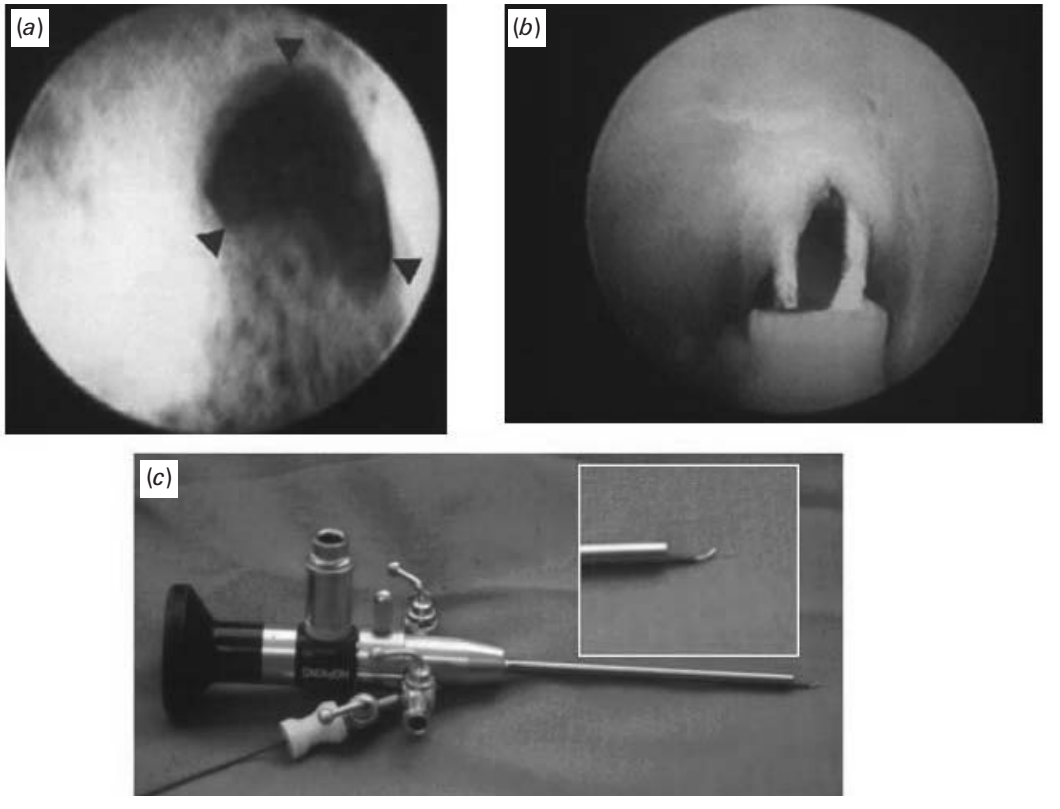

Figure 63.12 Incisions may be made at the 12, 5, and 7 o'clock positions (*a*) using either a resectscope (*b*) in an older child, or a bugbee electrode delivered by a 9 Fr cystoscope in the neonate (*c*).

father. Within hours, as the neonate is transferred to the NICU, we obtain an ultrasound, and if the findings are consistent with valves, we place a feeding tube in preparation for the VCUG. We then start antimicrobial prophylaxis with amoxicillin. A child who is stable from a pulmonary standpoint can then be prepared for valve ablation often within 48–72 hours of life.

If the boy has pulmonary hypoplasia and complex ventilatory requirements, prematurity precluding endoscopic manipulation, or significant postobstructive diuresis, we delay the valve incision and opt for a period of urethral catheterization. Sometimes in these settings, the infant's serum creatinine rises above the maternal creatinine as the degree of renal impairment becomes manifest. Usually, the diuresis is physiologic, but rarely, the rise in creatinine may reflect prerenal dehydration that follows postobstructive diuresis. In these situations, we recommend maintaining catheter drainage and allowing the medical condition to stabilize.

Surgical aspects

With the major advances that have taken place in fiberoptic technology, it is now possible to incise posterior urethral valves in all but very small premature neonates. Many approaches to valve incision have been described.[81] We use a bugbee electrode that can be passed through a 7.5 or 9 Fr neonatal cystoscope to apply cutting current to the valve leaflets at the 5, 7, and 12 o'clock positions (Figure 63.12). Even within our practice, some of us incise the valves only at 12 o'clock and others at 5 and 7 o'clock; some prefer a cold knife approach, whereas others prefer electrocautery. The principle of valve incision requires only that the surgeon disrupt the integrity of the valve. The valve itself does not need to be excised.

We consider performing a vesicostomy as the initial surgical intervention in the very premature neonate whose urethra will not accommodate an endoscope. We also consider this approach in a neonate whose creatinine has risen despite successful catheterization. In this setting, the vesicostomy minimizes lower urinary tract storage pressures and optimizes GFR.[82,83] We believe that a vesicostomy does not place the bladder at total rest; in fact the bladder does fill, and undergoes partial cycling. A vesicostomy allows for venting of high intravesical pressures as they develop, thus minimizing any transmission of pressure back towards the kidneys.

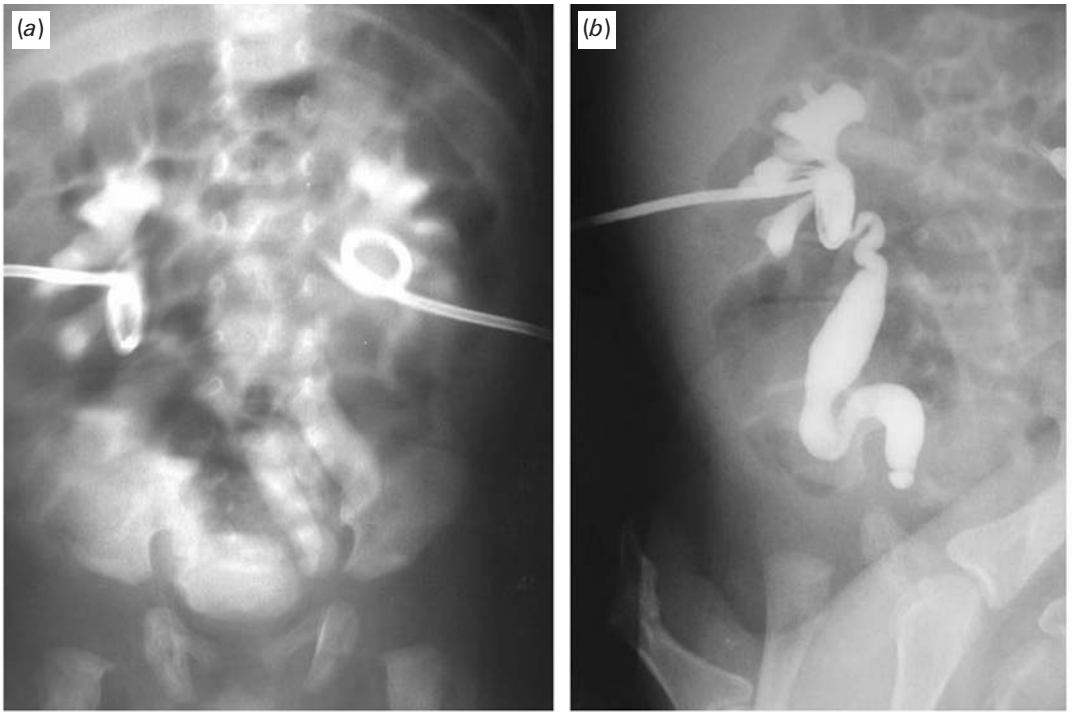

Figure 63.13 Upper tract imaging was ordered for this boy because the hydronephrosis failed to respond to primary endoscopic valve ablation. *(a)* The intravenous pyelogram reveals bilateral hydroureteronephrosis with delayed washout on the left. *(b)* An antegrade nephrostogram revealed a distal ureteral narrowing with impedance of flow into the bladder. At the time of these studies this patient was 2 months old, and had a serum creatinine of 0.7. Advocates for high urinary diversion to maximize GFR would note the increased resistance to drainage shown in *(b)* supports their approach. Advocates of the watchful waiting approach would counter with the following arguments: 1) If the nephrostomy tube were clamped, and one waited, contrast would flow into the bladder over time, because this is not a complete obstruction. 2) As the bladder experiences repeated filling and emptying cycles, it will heal and as the wall thickness diminishes, the resistance to antegrade flow will diminish. Our recommendations in this case called for the removal of the nephrostomy tubes, maintenance of antibiotic prophylaxis, circumcision, and serial imaging of the upper tracts at increasing intervals as the upper tracts decompressed.

One long-standing controversy in the management of patients with posterior urethral valves revolves around the use of high urinary diversion. Historically, a child whose renal function failed to improve, or even worsened following valve ablation, might undergo bilateral ureterostomy or pyelostomy. Following the surgery, the creatinine level often decreased, and thus high diversion has had its advocates.[83,84] Some believe that boys with severe outlet obstruction develop a secondary obstruction at the ureterovesical junction due to potential obstruction of the dilated ureter as it passes through the severely thickened bladder wall. If this were true, then high diversion would potentially reduce risk of renal damage from ongoing high pressure despite valve incision. If in such a setting, a nephrostogram is performed, it is possible to demonstrate an 'obstruction' at the ureterovesical junction (Figure 63.13). Although there are still centers where persisting dilatation of the upper urinary tract following successful valve ablation leads to consideration for upper urinary diversion, most pediatric urologists do not recommend high diversion despite evidence that resulting bladder function is good following undiversion.[83] Furthermore, high diversion prevents the bladder continuing its normal cycle of filling and emptying,[85] and many feel this contributes to a noncompliant bladder that is more difficult to rehabilitate later on prior to transplantation.[86–88]

Circumcision

We recommend circumcision in boys with posterior urethral valves. Wiswell's data suggest that febrile urinary tract infections are more commonly seen in uncircumcised males.[89,90] The consequences of urinary tract infection superimposed upon a dilated urinary tract with stasis and renal insufficiency should be enough to give every urologist ample cause to endorse circumcision and encourage it.

Nephroureterectomy

The traditional approach to the management of patients with unilateral high-grade vesicoureteral reflux and associated dysplasia (the VURD syndrome)[75] called for an initial valve incision followed by a nephroureterectomy. However, we have moved away from this approach, unless in the very unusual cases where we are forced by recurrent urinary tract infection. We believe the low-pressure venting into the non-functional system places less stress on the valve bladder that chronic increased pressure has compromised. For boys in renal failure, the native kidneys maintain fluid balance; renal failure with polyuria is easier to manage than anuria. It has been our experience that native nephrectomy is rarely required in these boys. If a nephrectomy is required, the ureters should be left behind for use in subsequent reconstructions.[91]

Ureteral reimplantation

Whereas up to 50% of patients presenting with valves show signs of vesicoureteral reflux on their initial VCUG,[82] successful valve ablation and bladder cycling lead to resolution in the majority of cases. Glassberg and co-workers have argued for management based on urodynamic data. They note that treating residual voiding dysfunction often leads to reflux resolution in this population.[92] If bladder function is optimal, then reimplantation can be performed successfully.[93] It is well established that reimplantation of dilated ureters into thick-walled bladders with associated voiding dysfunction carries a higher complication rate.[94] Thus, if correction of reflux in this patient population is desired, some consideration should be given to endoscopic injection.[95] In our own experience, ureteral reimplantations are almost never required in circumcised boys with successfully incised valves and may compromise bladder compliance, or potentially compromise a failing kidney.

Surgical complications

Surgical complications from endoscopic valve ablation are rare with the current generation of smaller high-resolution fiberoptic endoscopes. The feared complication of past years was a stricture induced by passing too large of an instrument through a tiny urethra. We almost never see this complication now that we have pediatric cystoscopes with a side port for a bugbee electrode. In the very small infant, if the available endoscopes cannot pass through the urethra, we consider a vesicostomy with plan for delayed valve incision.[81]

Short- and long-term outcomes of posterior urethral valves

Short-term complications seen following posterior urethral valve incision may include urinary retention and renal failure.[82,96] If voiding is not complete and urinary tract infection ensues following posterior urethral valve incision, short-term use of clean intermittent catheterization (CIC) may become necessary. Remember that following decompression of a dilated urinary tract, if vesicoureteral reflux is present, there may be ample storage volume in the dilated ureters and renal pelvis. In this setting, if CIC is performed at too frequent an interval, the bladder may never distend to a volume required to trigger voiding in the infant. Rarely, an associated bladder diverticulum may compress or distort the trigone and bladder neck. In this case, surgical excision of the diverticulum may be required. In general, if urinary retention is noted postoperatively, catheterization for 24 hours followed by a repeat voiding trial is nearly always successful. The number of posterior urethral valve patients who have true myogenic failure is small.[97]

In some boys, the neonatal course is complicated by renal failure. In many of these cases, the more immediate life-threatening problem is respiratory failure brought about by hypoplastic lungs (see Figure 63.1). Many of these boys are now detected before birth by fetal sonography, and the pulmonary complications may be minimized either by shunting or amniotic fluid infusions. Extracorporeal membrane oxygenation (ECMO) has been used for these boys until they can be managed with conventional ventilatory support.[98] The majority with posterior urethral valves who require ECMO support in the neonatal period develop ESRD and require renal transplantation later. Tremendous progress has been made in the management of neonatal renal failure over the past 20 years. Both hemodialysis and peritoneal dialysis are now feasible in this population. In the past, renal transplantation was rarely undertaken for any patient <1 year old. Today, more and more centers offer renal transplantation to babies in the first year. Although technically feasible, given the discrepancy between the organ size and the total body volume of the recipient, such procedures are complex. For this reason, as well as the desire to minimize the years of immunosuppression, every effort is made to optimize renal function, avert dialysis, and let the child develop without the transplant as long as possible.

Approximately 20–30% of patients with posterior urethral valves go on to develop ESRD. Studies suggest that if by 1 year old the serum creatinine level has reached a nadir value of ≤0.8, ESRD will be avoided.[82] Although such renal insufficiency is present in the neonatal period, there is usually enough GFR to support growth and development. The pediatric urologist and nephrologist must work together to closely follow boys whose creatinine level approaches these values. On occasion, these boys suffer from tubular acidosis, and require bicarbonate replenishment. For those with more advanced renal insufficiency, growth hormone may be required. As the renal failure advances, calcium metabolism and bone development must be closely monitored. Long before the time for transplantation approaches, the urology and nephrology team must begin to address the function of the lower urinary tract, and its ability to safely sustain an allograft with low storage pressures.

Most series report a substantial delay in the acquisition of daytime and night-time continence for all patients with posterior urethral valves.[82,96] For patients with less severe posterior urethral valves, the bladder and renal function combined allow for continence, usually around 6–7 years old. However, persistent urinary incontinence is an ominous sign in patients with a diagnosis of posterior urethral valves.[99] Given the pathophysiology of upper and lower urinary tract obstruction outlined at the beginning of this chapter, this incontinence is more readily understood. Because of the bladder wall fibrosis and poor storage capabilities, an increasing volume of urine is stored at higher pressures within the upper urinary tract. The severe polyuria that these patients exhibit due to distal tubular injury in utero worsens this problem. Ironically, the boy himself may also unwittingly aggravate the condition in his desire to be dry. As he struggles to achieve dryness by suppressing the desire to void, and retain urine, he contributes to upper tract dilatation and increasing storage pressures. For many boys, a regimen of timed voiding is effective. In others with upper tract dilatation, double voiding will safely result in dryness. Instructing the boy to void in the ultrasound suite, with pre- and postvoid views of the kidneys, ureters, and bladder provides a powerful teaching tool for the boy who would benefit from double voiding and his family.

It has become clear in recent years that, for many of these patients, overnight catheter drainage[100,101] and CIC will provide continence, lower storage pressures, and preserve renal function. For all these reasons, a critical time to follow a boy with posterior urethral valves closely is around the time he begins to express an interest in potty training. This is even truer for boys with borderline renal function.

Videourodynamics

For the posterior urethral valve patient who has persistent urinary incontinence, or is approaching ESRD, videourodynamics offers an invaluable tool to optimize the chances for achieving dryness[92,102] and

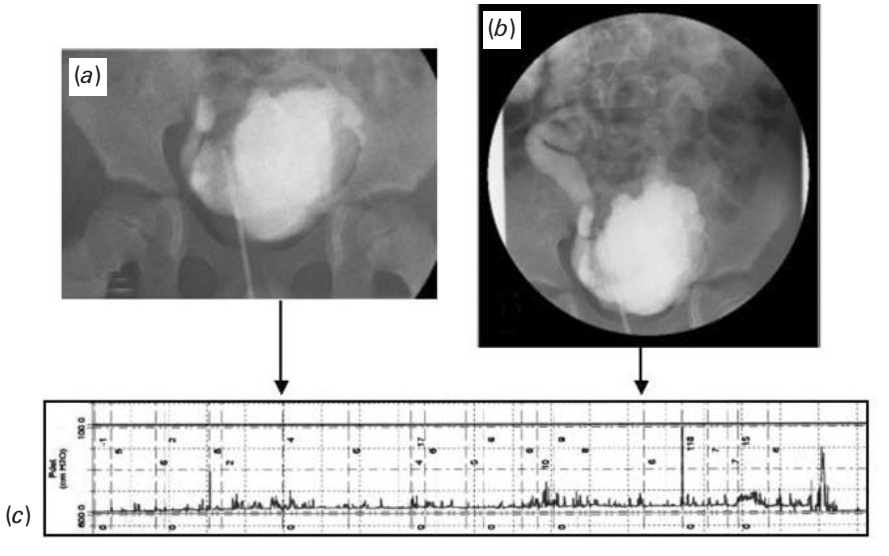

Figure 63.14 This videourodynamics study demonstrates the benefit of the fluoroscopic examination (*a*, *b*). At first glance, it appears to be a very compliant cystometrogram (*c*); however close examination reveals that compliance is augmented by the reflux into the upper tracts (*b*).

for successful transplantation. Before ordering videourodynamics, it is essential to have the patient and family complete a thorough diary, which includes not only the urinary output but also the fluid intake. This helps to determine the average urinary volume produced on an hourly basis by day and night, and what voiding frequency will be required. In contrast to conventional urodynamics, a videourodynamics study will help to determine what part of the storage capacity is provided by the bladder, and compare that with is contributed by the ureters, renal pelvis, and calices.

We have demonstrated this concept with the study shown in Figure 63.14. This study, if done conventionally, would suggest that the boy has a very compliant bladder. In fact, when the video images are considered, it is clear that the bladder has poor compliance and there is high-grade reflux early in filling. The high-grade reflux into his native kidneys augmented this boy's storage capacity and masked poor bladder compliance. Despite attempts at double and triple voiding, his diurnal urinary incontinence persisted in part due to his polyuria. He resisted our attempts to teach him urethral CIC, which is typical in this population of patients with a sensate perineum and a dilated posterior urethra (see Figure 63.9). Based on this study, we recommended an appendicovesicostomy to allow intermittent catheterization every 2–3 hours by day, and overnight catheter drainage. As long as this boy was compliant with his daytime catheterization schedule, he remained dry. Following transplantation he is continent due in large part to the improved concentrating ability of his allograft. In this case, the videourodynamic study altered this boy's care in two ways: first, the study made it clear that native nephroureterectomy would compromise his ability to achieve safe storage pressures; secondly, the large residual urine measured by the study reflected storage in his upper tracts that would not respond to double-voiding regimens. Given these findings, clean catheterization via an appendicovesicostomy offered him the optimal management for achieving dryness in the short term, while preparing for the inevitable renal transplant that followed.

Postobstructive diuresis

Boys with a history of posterior urethral valves often have persistent dilation of the upper urinary tract that worsens as they begin to toilet train. For some boys, the imposition of daytime dryness achieved by delaying voiding and conscious use of the external sphincter places additional burden on the upper tracts. This worsens during sleep. What produces a reward for the child in terms of dry sheets in the morning and clean underwear at the end of the day may contribute to worsening of renal function. For some boys this leads to a cycle (Figure 63.15) in which increasing bladder storage pressures result in higher renal pelvic pressures. This in turn aggravates renal medullary concentrating ability, which is already compromised,[38] and thus results in additional diuresis.

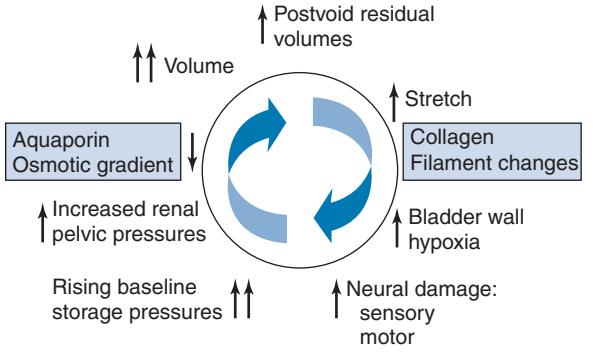

Figure 63.15 The integration of upper and lower urinary tract dysfunction in boys with posterior urethral valves. The cycle of gradual increasing postvoid residual volumes leads to increased resting prevoid pressures, which in turn leads to increasing renal medullary pressures. The resulting loss of concentrating ability results in increasing diuresis, which aggravates the cycle by subjecting the bladder to increasing stretch.

Clinical and experimental evidence supports these concepts. In a videourodynamic assessment of partial bladder outlet obstruction, decompensated rabbit bladders had good compliance, defined as $\Delta V/\Delta P$. They also required much larger volumes (with a higher prevoid baseline pressure) to initiate their voids, which were small and associated with high residuals. Within this group, the postvoid residual urine recorded exceeded the infused volume.[103] This led us to consider these cystometrograms on an individual basis, and to classify them according to their baseline pressure before voiding. For the subset of obstructed bladders (30%) in which the baseline pressure $>10\ cmH_2O$, the postvoid residual urine exceeded the infused volume by an average of 30 ml (Figure 63.16). How could the residual volume exceed the infused volume by nearly 40%? In performing these experiments, we emptied the bladder under fluoroscopic control before initiating slow-fill cystometry at 1–2 ml/min. During the filling period, the diuresis from the upper tracts was pronounced in those bladders with an elevated baseline pressure

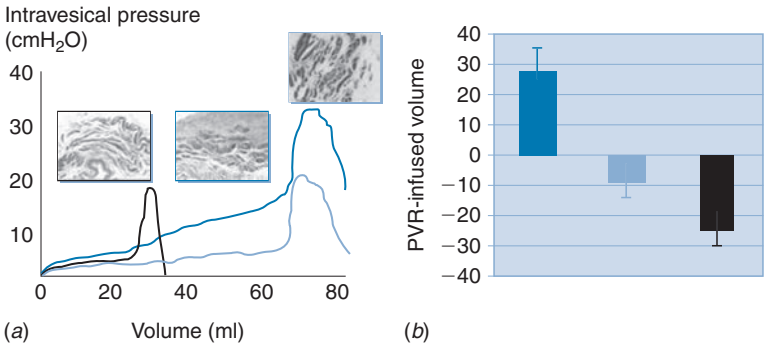

Figure 63.16 Experimental work demonstrates the relationship between a non-compliant bladder and postobstructive diuresis. (*a*) Following partial bladder outlet obstruction in rabbits, we performed videourodynamics free of any sedation 24 hours after placement of bladder and peritoneal catheters. For the sham control (——) we recorded a normal slow-fill CMG terminating in a voluntary void to completion. For decompensated bladders, we observed two populations of curves. In one group of bladders, compliance was preserved if expressed as $\Delta P/\Delta V$; however, the resting pressure just before voiding was higher (——). However for a second group of decompensated bladders, a non-compliant pattern was observed with a much higher resting pressure before void (——). In each instance, we recorded an accurate postvoid residual with fluoroscopic confirmation. Note the increased deposition of extracellular matrix elements in the two decompensated bladders. (*b*) If one subtracts the infused volume from the postvoid residual, and exceeds zero, this is evidence of a diuresis that occurs during bladder filling. We observed the presence of a postobstructive diuresis only in those non-compliant decompensated bladders whose resting pressure before voiding exceeded 10 cmH_2O. (Adapted from Stein,[104] with permission.)

before voiding. Although the majority of these bladders demonstrated 'good compliance', these rabbits were spending most of their time at the far right of their cystometry curves, and thus subjecting their upper tracts to the same higher baseline pressure. This postobstructive diuresis was also observed in 30% of the rabbits following reversal of outlet obstruction in a subsequent group of experiments.[104]

We have observed similar findings in boys with posterior urethral valves. During a videourodynamic study of a boy with urinary incontinence following valve ablation, we noted that despite having initiated the study by aspirating all urine from the system, the postvoid residual urine exceeded the volume infused. We also observed this phenomenon in another boy with posterior urethral valves in whom we had created a unilateral end-cutaneous ureterostomy. We recorded this boy's ureterostomy output and correlated it with the catheterization status of the bladder. When this boy slept without an indwelling catheter, we recorded larger volumes of urine from the ureterostomy. In contrast, when sleeping with an indwelling catheter, the overnight volumes recorded from the ureterostomy dropped by almost 40%. This finding supports our conclusion[100] and that of others[101,105,106] who feel that overnight catheter drainage can eliminate a substantial volume and hence pressure burden on the upper tract (Figure 63.17). Taken over a period of time, and with recovery of some concentrating ability, the total 24-hour urine volumes often drop, offering both the benefits of improved daytime continence and optimizing renal function.

Pretransplant evaluation

Even today, despite antenatal diagnosis, the incidence of ESRD for patients with posterior urethral valves remains at about 20%. The pediatric urologist caring for these boys must continue to remain actively involved with the nephrology transplant team. Boys undergoing transplantation with a poorly functioning bladder have higher complication rates and graft loss than those in whom lower urinary tract function has been optimized.[107,108] We recommend videourodynamic assessment for any boy in whom transplantation is imminent. This allows us to calculate the safe bladder storage pressures and to assess whether CIC is required. Videourodynamic studies may also reveal that high-grade reflux into the native ureters provides additional compliance to the system (see Figure 63.14). For this reason, we rarely recommend nephrectomy. The principal indications for pretransplant native nephrectomy are the presence of severe polyuria or hypertension that is difficult to control. We have rarely witnessed new urinary tract infection into the native kidney following transplantation if infection was not common before the transplant. If

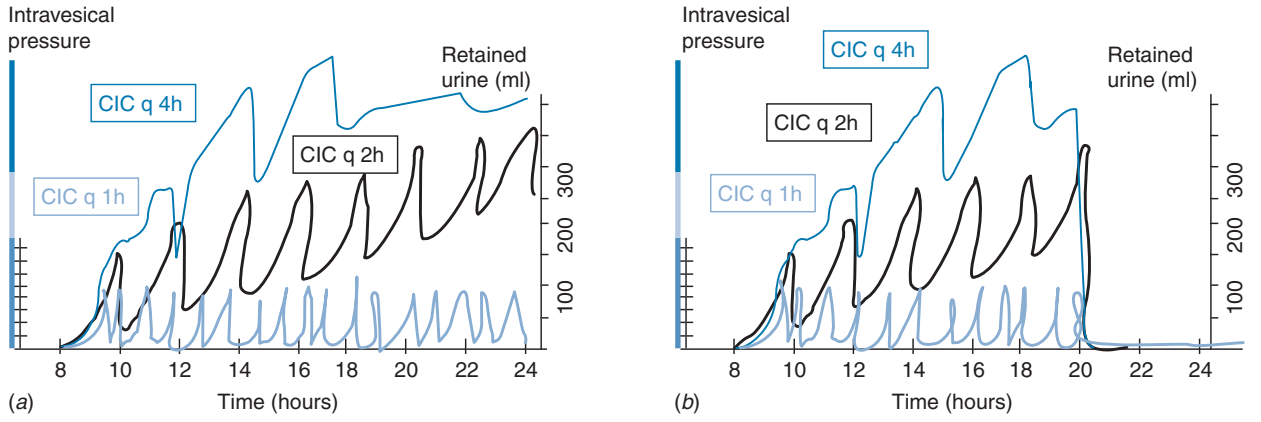

Figure 63.17 The concepts of (*a*) a safe pressure storage zone and (*b*) the role of overnight catheter drainage. As is shown in both (*a*) and (*b*), maintaining a safe storage pressure (mid-blue on the left) for a patient with this severe polyuria is possible only with a regimen of clean intermittent catheterization (CIC) at 1-hour intervals. As the intervals move to CIC at 2-hour intervals, the daytime hours drift upwards from the mid-blue to the pale-blue pressure zones. However, at 4-hour CIC intervals, the dark blue zone of high intravesical pressures is reached during the waking hours, and prolonged exposures to high dark blue zone pressures are maintained during the overnight hours. However, with overnight catheter drainage (*b*), the hours of exposure at high pressure at night are minimized. An additional benefit with this particular patient was that renal-concentrating ability improved and the total volume produced in 24 hours dropped, making daytime dryness easier to attain and at lower intravesical pressures.

nephrectomy is indicated, we preserve the ureters for catheterization, augmentation, or for anastomosis to the transplanted kidney should problems arise within the transplanted ureter.

If videourodynamics reveals that the bladder capacity must be expanded to provide safe storage pressures, ureteral augmentation is an option.[109] Very rarely, augmentation using a bowel segment may be necessary. In the past, dogma required that total bladder reconstruction, including augmentation if required, must occur before transplant. Our experience has been different. We have been pleased with the results of transplantation to the vesicostomy in the unusual cases where low bladder volume and poor compliance resulted in lower tract diversion. Under these conditions the transplant team should not hesitate to reimplant the transplant ureter into a diverted bladder that is draining via a vesicostomy.[110] With this approach, we have successfully postponed reconstruction with the associated CIC to an age-appropriate date, and in some cases, with the addition of overnight catheterization, we have avoided the need for augmentation altogether.

Prune belly syndrome

64

R Guy Hudson and Steven J Skoog

Introduction

Prune belly syndrome is classically defined by three abnormalities: deficiency of the abdominal wall musculature, bilateral cryptorchidism, and a dilated, dysmorphic urinary tract (Figure 64.1). The scope of involvement of the genitourinary system, combined with the visible appearance of the abdominal wall, sets the stage for the intense interest that surrounds this developmental anomaly.

A rich history surrounds the recognition of the essential components of the prune belly syndrome (Table 64.1). In 1839, Frolich noted the abdominal wall 'tumidity'.[1] Parker, in 1895, recognized the essential element of the syndrome to include a large flaccid abdominal wall with absent musculature, undescended testes, and a hypertrophied bladder and dilated renal collecting system without urethral obstruction.[2] William Osler is credited with giving the syndrome its name 'prune belly' in 1901. Prune belly syndrome is, at present, the most widely accepted appellation.[3] Other popular synonyms – Eagle–Barrett syndrome, urethral obstruction malformation complex, the triad syndrome, abdominal muscle deficiency syndrome, and mesenchymal dysplasia syndrome – reflect the etiologic biases of the respective authors.[4–7]

Prune belly syndrome is not confined to the male gender. Females constitute about 3–5% of recorded cases.[8] The strict criterion of cryptorchidism would effectively eliminate the syndrome in female patients, but the descriptive term 'prune belly' is applicable. Omphalocele and bladder outlet obstructive lesions are often seen in female patients with prune belly syndrome.[9] In a review by Reinberg et al, 40% of female patients had anorectal anomalies and the perinatal mortality was 40%.[10] The term 'pseudoprune' has been suggested to define females and males who do not have the complete triad of prune belly syndrome.[3] Hence, males with a lax abdominal wall but without undescended testes or without a dilated urinary tract and all affected females are considered pseudoprunes. The principles of management in females are essentially the same as in the male patient. The underlying uropathy and clinical course in patients with pseudoprune belly syndrome are unpredictable and in one series 63% went on to renal failure.[11]

The incidence of prune belly syndrome is 1 in 29 000 to 1 in 40 000 live births.[12,13] An increased incidence has been reported in Nigeria[14] as well as in Saskatchewan, Canada.[7] In a population-based study from New York State the live birth prevalence was 3.2 per 100 000. Twins, blacks, and children born to younger mothers appear to be at higher risk.[15] Maternal

Table 64.1 History of prune belly syndrome

Year	Author	Discovery
1839	Frolich	Described abdominal wall abnormality
1895	Parker	Recognized all three components of the syndrome
1901	Osler	Coined the name prune belly syndrome
1903	Strumme	Proposed obstructive hypothesis of prune belly syndrome
1961	Nunn and Stephens	Proposed theory of mesodermal arrest as an etiology of prune belly syndrome

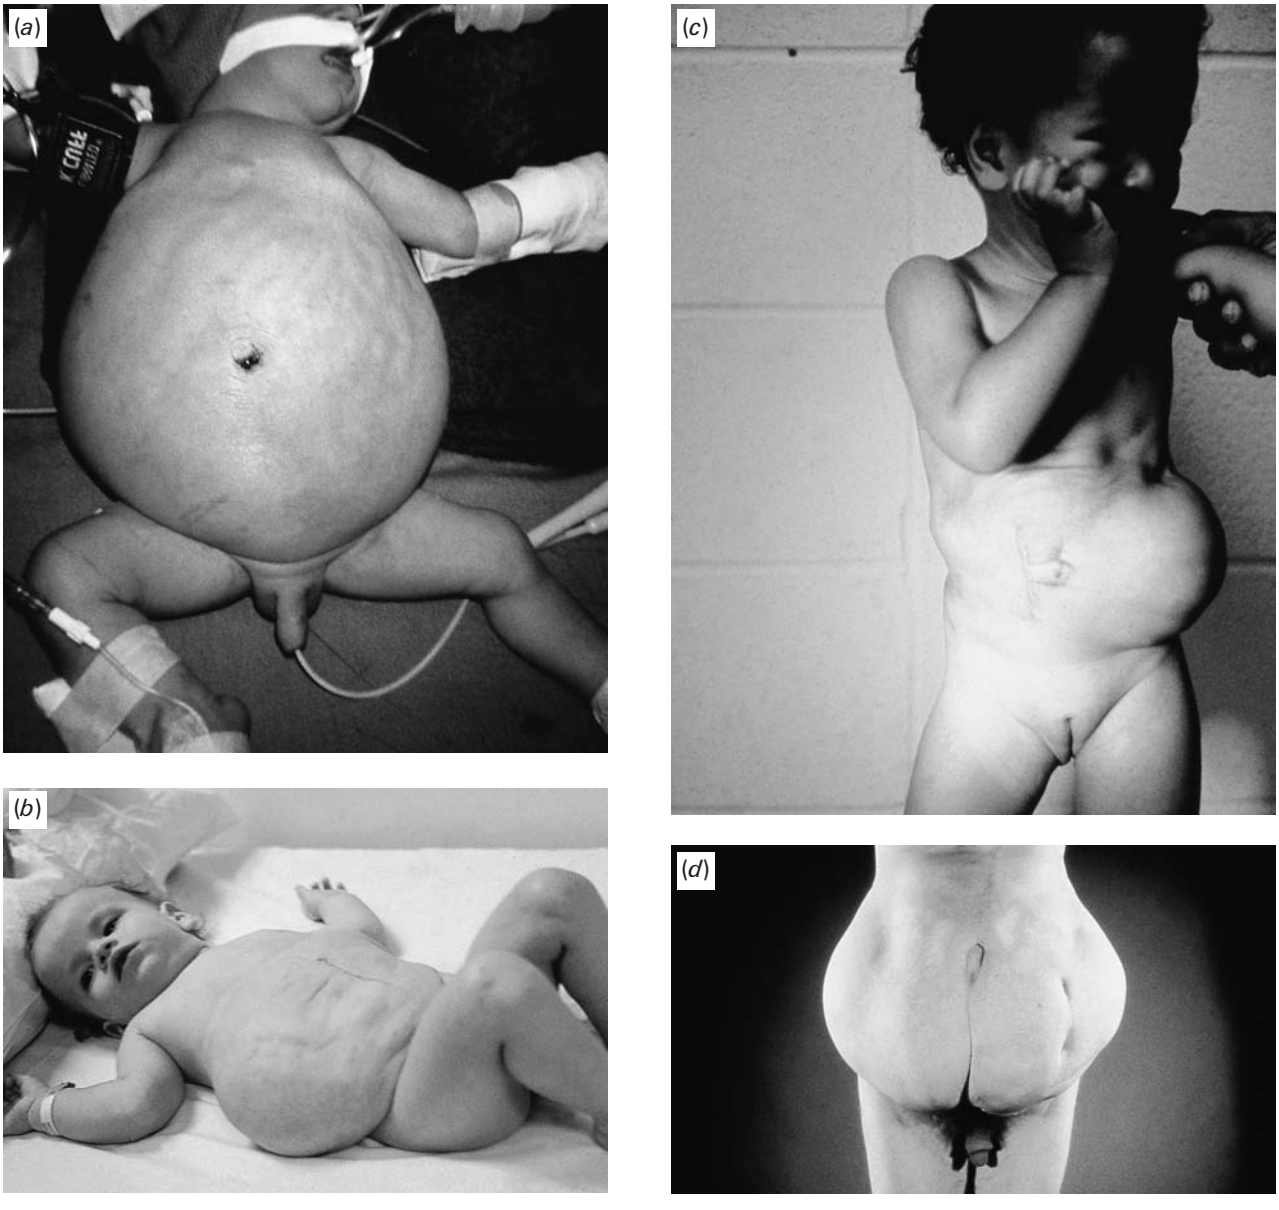

Figure 64.1 (*a*) A newborn with prune belly syndrome, urinary ascites, and pulmonary hypoplasia. Outline of the bowel is visible through the abdominal wall. (*b*) A 6-month old infant with prune belly syndrome before comprehensive reconstruction. (*c*) A 4-year-old female with hemiprune belly. (*d*) An adult with prune belly syndrome exhibiting 'pot belly' configuration.

cocaine abuse during pregnancy has been associated with prune belly syndrome.[16]

Unfortunately, patients with prune belly syndrome can have many associated conditions that have a significant clinical impact. These can include pulmonary hypoplasia, renal dysplasia/insufficiency, cardiac anomalies, lower extremity musculoskeletal malformations, imperforate anus, and intestinal malrotation/malfixation. These conditions impart a significant morbidity in prune belly patients and often influence urologic management.

One major area of controversy in the management of prune belly syndrome is the role of surgical reconstruction. Early series stressed the importance of relief of obstruction and stasis by high ureterostomies or catheter drainage. Indwelling catheter drainage often met with infectious complications, with an additional 30% mortality reported in the first 2 years of life.[17,18] Later reports of successful, early urinary reconstruction demonstrated both improved urinary drainage and radiologic configuration of the urinary tract. Long-term follow-up demonstrated stabilization of renal function.[6,19–22]

Prevention of urinary infection and preservation of renal function may also be achieved with 'watchful waiting.'[23–26] With the development of improved prophylactic antibiotic therapy and utilization of advanced urodynamic equipment, the need for extensive tailoring of the urinary tract has been questioned. In fact, Woodhouse et al reported a normal serum creatinine in 27 patients with prune belly syndrome who had limited surgical intervention over a 29-year period.[27] However, mindful of psychological and fertility considerations, current practice dictates an early surgical role in correction of the abdominal wall defect and the cryptorchid testes.[28–31]

A further improvement in the treatment of prune belly syndrome has been the application of dialysis and renal transplantation. Transplantation offers hope to patients with poor renal function due to initial renal dysplasia or progressive chronic renal insufficiency, despite appropriate urologic intervention.

This chapter reviews proposed etiologies of the syndrome and associated malformations, and illustrates the spectrum of management of these patients.

Theories of etiology and embryogenesis

Inheritance

A variety of genetic inheritance patterns have been suggested in prune belly syndrome. The majority of cases are sporadic and have a normal karyotype.[13,32] Prune belly syndrome has been reported in male siblings, cousins, and twins.[14,33–36] However, the majority of affected twin pairs are discordant for prune belly syndrome, which speaks against a purely genetic etiology. Ives noted 11 pairs of twins discordant for the syndrome: six were monozygous and five were of unknown zygosity. Of the 250 cases of prune belly syndrome reviewed, 11 cases or 4% occurred in twins, compared with the 1.25% incidence of twinning in the general population. Unequal division of mesoderm cells, occurring at the primitive streak formation, may explain the discordant monozygotic twinning phenomena.[7]

Williams was one of the first to suggest that prune belly syndrome was due to a sex-linked recessive trait. This would explain the male predominance of the syndrome, its occurrence in male siblings, in concordant twins, and in association with Turner's syndrome.[23,37] The presence of prune belly syndrome in three females with documented 46,XX karyotype speaks strongly against this pattern of inheritance.[38]

Autosomal dominant and autosomal recessive inheritance have also been reported.[14] Male predominance, lack of consanguinity, and lack of extensive pedigrees in new cases due to associated infertility, make any association with single gene inheritance uncertain at this time.[13] Riccardi and Grum suggested a two-step autosomal dominant mutation with sex-limited expression that partially mimics X-linkage. This genetic inheritance pattern would explain male predominance, as well as the small number of affected family members.[35]

Specific chromosomal abnormalities are rare. Trisomy 18 and trisomy 21 have been demonstrated in prune belly syndrome.[39–42] Trisomy 18 is also associated with other genitourinary abnormalities, including renal dysplasia and hypoplasia, horseshoe kidney, duplication anomalies, and persistent nodular renal blastema.[43] A cause-and-effect relationship is only speculative. A careful analysis of incidence and birth rates suggests that these are independent events, occurring together by chance alone.[44]

An association with Turners' syndrome suggests that the gene responsible for the syndrome may be located on the X chromosome and is recessively transmitted. However, it probably represents the occurrence of the prune belly phenotype in the female as a result of other causes of abdominal distention, such as impaired lymphatic development with chylous ascites.[4,14,37] Although mosaicism for a monosome of chromosome number 16 in two male siblings with prune belly syndrome has been documented, its importance etiologically cannot be determined.[45] An extracentric chromosomal fragment was reported in association with prune belly syndrome. However, the same aberration was present in two phenotypically normal male family members.[46]

Prune belly syndrome has been reported in association with other syndromes, chromosomal aberrations, and conditions. Perlman syndrome, Beckwith–Wiedemann syndrome, VACTERL association, Pfeiffer syndrome type 3, and megacystis–microcolon–intestinal hypoperistalsis syndrome have all been described in patients with prune belly syndrome, suggesting the possibility of a common pathogenesis.[47–50]

Fetal development

Three major theories have been proposed to explain the clinical features of the prune belly syndrome. As with most theories, none completely explains the entire constellation of findings in the syndrome, and all are marred by conjecture and speculation.

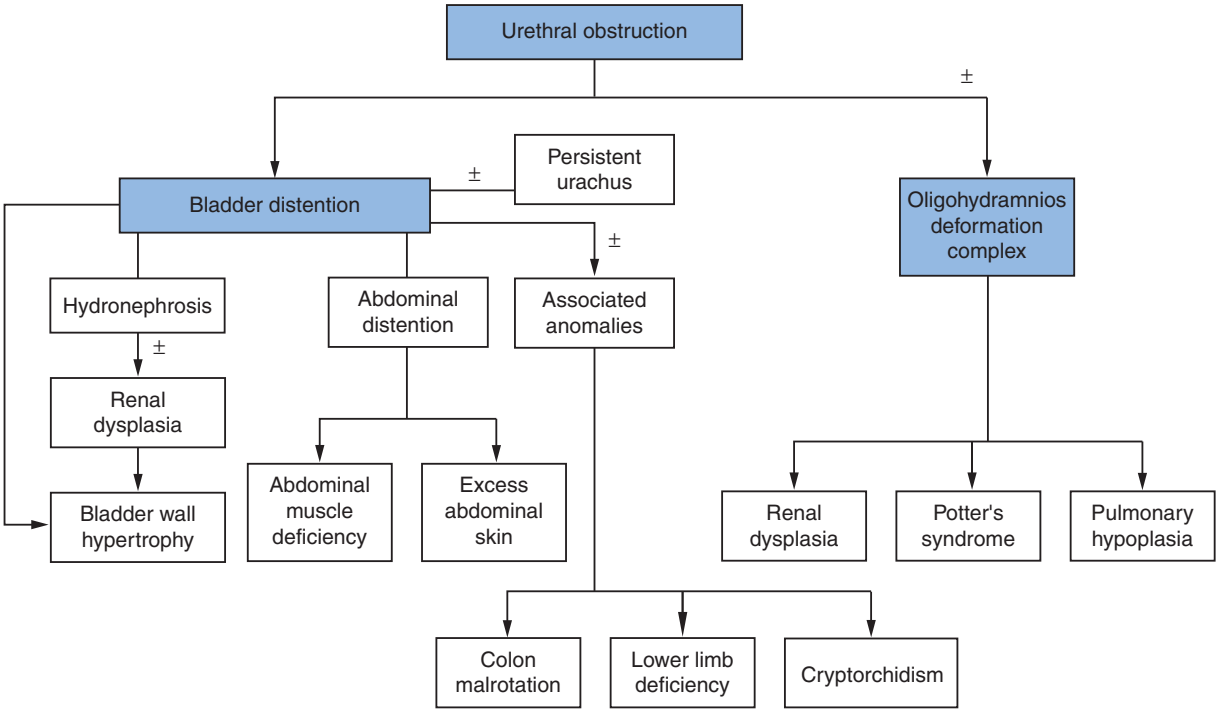

Figure 64.2 Urethral obstruction, whether anatomic or functional, is a proposed etiology of prune belly syndrome and its associated anomalies.

Fetal outlet obstruction

In 1903, Strumme proposed that prune belly syndrome was the final expression of an obstructive urologic lesion producing significant back pressure at a critical time during development. The dilatation of the urinary tract and secondary pressure atrophy of the abdominal wall produced the clinical features common to prune belly syndrome (Figure 64.2).[51] Subsequent clinical reviews reflected this belief and called attention to the need to alleviate the obstructing lesions commonly found in the posterior urethra.[18,52–54] Improved methods of radiographic diagnosis of obstruction with the voiding cystourethrogram (VCUG), postmortem anatomic en-bloc dissections, and the application of urodynamic studies cast doubt on the anatomic presence of obstruction.[5,23,24,55] More recent clinical reports have found evidence of an obstructing lesion in 10–20% of patients, contrasted with up to 80% in earlier series.[26,52] It has been proposed that those infants with the most severe manifestations of the syndrome have the 'lethal variant' (an anatomic obstructing lesion), leading to pulmonary hypoplasia, renal dysplasia, and death.[53] This distinction is particularly important when studying the theories of pathogenesis, as most articles that indicate obstruction as the primary cause are based on autopsy information.[54,56–59]

The source of the obstruction may be true areas of stenosis, atresia, valves, or pinpoint diaphragms at the junction of the posterior and membranous urethra. Recent theories have suggested a 'functional obstruction' present in utero, secondary to prostatic hypoplasia, as the specific etiology of the syndrome. This 'obstruction' is thought to be the result of conformational changes in the prostatic urethra during voiding, creating a valve-like mechanism.[57,60] Another etiology suggested in prune belly syndrome is a transient obstruction at the junction of the glandular and penile urethra. This was based on evidence of anterior urethral dilatation in patients with prune belly syndrome measured on radiographs from a VCUG. Comparisons were made with children with urinary tract infections and children with posterior urethral valves.[61] This theory is supported by the high incidence of megalourethra seen with prune belly syndrome.[62,63]

The obstructive theory contends that the abdominal wall findings are secondary to the pressure effects of the distended bladder on the developing myotomes of the abdominal wall. The muscles directly over the bladder – transversus abdominis, obliques, and lower rectus – are most severely affected, supporting this

theory. However, histologic studies and electron microscopy of the abdominal wall do not demonstrate a pattern of atrophy, but one of developmental arrest.[64–66] In addition, the absence histologically of any aponeurotic layer of the affected muscles opposes an atrophic cause.[66]

Evidence from prenatal ultrasound in patients with prune belly syndrome and other disease processes associated with the prune belly phenotype suggest that the abdominal wall laxity is due to abdominal distention. A transient ascitic distention explains patients with the syndrome who lack evidence of urethral obstruction.[4,67–70] Urinary ascites has been demonstrated in utero in patients with prune belly syndrome. The urine is theorized to leak into the abdomen via the distended urinary tract and spontaneously reabsorbs at the end of gestation, which explains its clinical absence at birth.[67,68,71–73] Other causes of in-utero abdominal wall distention and the prune belly phenotype include non-immune ascites, intestinal duplication, posterior urethral valves, amniotic band syndrome, visceromegaly, polycystic kidneys, impaired lymphatic drainage in Turner's syndrome, giant liver cyst, and cystic adenomatoid malformation of the lung.[4,69,74–76]

The 'urethral obstruction malformation complex' is applied to the theory of fetal outlet obstruction as the etiology of prune belly syndrome. The timing and severity of the obstructive phenomena is critical. Distension of the urinary tract at 13–15 weeks of gestation could produce the degenerative changes in the abdominal wall and urinary tract, preventing gut rotation and prostatic development.[77] This broader application of Strumme's original hypothesis fails to explain (1) the lack of hypertrophy and hyperplasia present in the obstructed urinary tract, (2) the replacement of smooth and skeletal muscle by fibrous and collagenous tissue, (3) normal or low intravesical pressures assessed urodynamically, (4) absent obstruction but presence of renal dysgenesis in the majority of patients, (5) other causes of in-utero outlet obstruction not associated with abdominal wall laxity, and (6) the excessively high incidence of cryptorchid testes. All these factors are common in prune belly syndrome and cannot be completely explained on the basis of obstruction alone.[5,23,55,78,79]

Theory of mesodermal arrest

This theory suggests that the etiology of prune belly syndrome is an embryologic aberration of mesenchymal development (Figure 64.3).[5] Urinary tract obstruction occurs in some patients as a consequence of the primary defect and may increase the pathologic severity.[77] Stephens and Gupta have proposed that the genitourinary tract, the testes, and the abdominal wall would be vulnerable to a mesodermal defect occurring between the 6th and 10th weeks of gestation.[80] A noxious insult occurring when the lateral plate mesoderm has already extended to the midline, with failure of myoblast differentiation and migration ventrally and caudally, would explain the abdominal wall findings.[56] At the same time, the urinary tract is developing from the visceral layer of the lateral plate mesoderm. The same insult would impair differentiation of the mesoderm that forms the smooth muscle of the urinary tract, resulting in the characteristic dilatation and dysmorphic features common to the

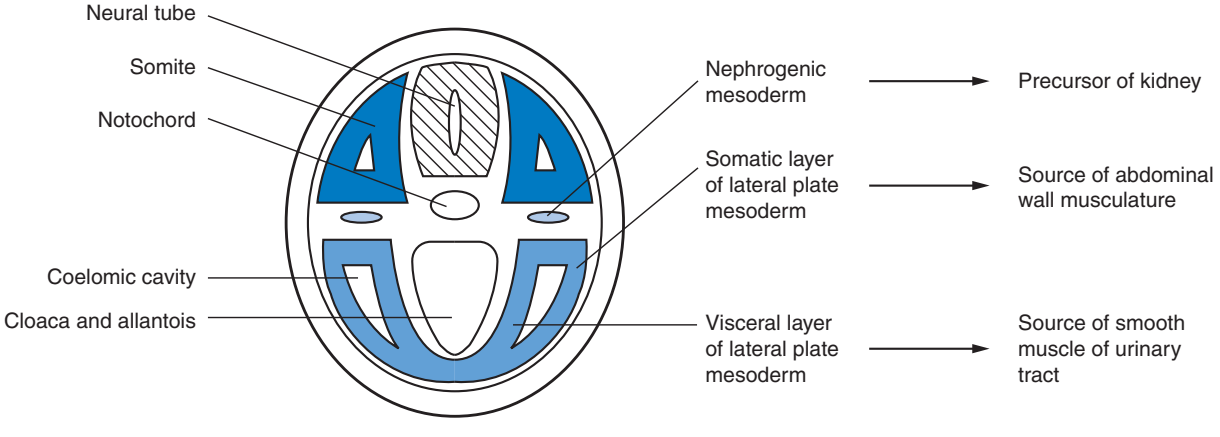

Figure 64.3 Cross section of a fetus at 6–10 weeks of gestation. An embryologic insult to both layers of the lateral plate mesoderm and the nephrogenic mesoderm could explain the majority of findings seen in the prune belly syndrome.

syndrome. The kidneys are concurrently differentiating from the para-axial mesoderm. A defect in induction by the ureteral bud or an abnormality in the metanephric blastema, with or without subsequent urinary tract obstruction, would account for the renal dysplasia commonly associated with prune belly syndrome.[12,56,80]

Some authors have suggested that this insult must occur early in the 3rd week of embryogenesis, at the primitive streak stage of development. At the division of the embryonic disk, an unequal distribution of mesoderm could explain the discordant occurrence in monozygotic twins.[7] This localized defect in mesodermal development would also explain the abnormalities seen in the prostate, urethra, and in testicular descent. According to this theory, the prostatic hypoplasia with poor glandular development, and abnormalities in the mesenchyme of the testicular gubernaculum, result in unresponsiveness of these tissues to hormonal stimulation.[56,81–83] This unresponsiveness of the gubernaculum to hormonal stimulation, the diminished intra-abdominal pressure, and potential mechanical obstruction by an enlarged bladder, all contribute to the maldescent of the testes in the prune belly syndrome.

The mesodermal arrest theory is further supported by histologic findings in the abdominal wall, the urinary tract, and the male genital tract. The abundance of fibrous tissue, collagen, and connective tissue, in association with sparse smooth muscle throughout the urinary tract, indicates an inherent problem with mesodermal differentiation. Bladder outlet obstruction, as seen in posterior urethral valves, results in hypertrophy and hyperplasia in the urinary tract, with normally developed seminal ducts, seminal vesicles, and prostate glands proximal to the obstruction. These features are noticeably absent in the prune belly syndrome.[5,55,65,80,81,84] The absence of anatomic obstruction in the majority of patients and the demonstration of urodynamically unobstructed urinary tracts support this theory. This theory also provides an adequate explanation for the high association with megalourethra.[5,63,85]

Nevertheless, the mesodermal arrest theory does not explain the male predominance of the syndrome. It also fails to explain the myriad associated anomalies and the presence of the abdominal wall abnormalities with a normal urinary tract. In addition, obstructive urethral lesions, whether anatomic or functional, are sometimes associated with the syndrome. The development of an animal model, created by urethral ligation, has been reported with all the features of the syndrome.[57,60,86]

The yolk sac theory

Stephens proposed an additional theory to explain the features of the prune belly syndrome. It is based on an error in embryogenesis of the yolk sac and allantois. Inherent in this theory is the contention that the bladder and prostatic urethra are derived, to a greater degree than customarily accepted, from the allantois. If an abnormally large amount of the yolk sac is retained inside the embryo, due to overgrowth of the lateral folds of the discoid embryo, it could affect the development of the abdominal wall, resulting in the prune belly phenotype. A critical aspect of this theory is the overdevelopment of the allantoic diverticulum. This structure grows out from the yolk sac contiguous with the body stalk. If it becomes excessively large due to the oversized intra-abdominal yolk sac, it would become incorporated into the urinary tract as the redundant enlarged urachus, bladder, and prostatic urethra which characterizes the syndrome.[66,80] Unfortunately, this theory does not explain the errors in development of the upper urinary tract or male genital tract.

Spectrum of disease

Prune belly syndrome represents a spectrum of disease severity. Classification systems based on this clinical spectrum have been formulated by numerous authors and all take into consideration initial and subsequent renal function.[31,54,87,88] The classifications have similar, clinically distinctive parameters to segregate the patients prognostically. The clinical classification of prune belly syndrome provides a framework for a more rational approach to overall management, which is determined on an individual basis.[12] Based on Woodard's classification, three major categories can be broadly defined (Table 64.2).

Category I patients exhibit the most severe form of the prune belly syndrome, with pulmonary hypoplasia and severe renal dysplasia. Most patients in this category do not survive beyond the first few days of life. The stillborn births are often associated with oligohydramnios and the classic features of Potter's syndrome are observed.[89,90] In this subset of patients with severe renal dysplasia, high urinary diversion, when performed, is generally to no avail.[6] Initial normal serum creatinine progressively rises in spite of urinary diversion. These patients may also have complete urethral obstruction or atresia, which is the 'lethal variant' of the syndrome unless associated with a patent urachus.[53]

Table 64.2 Spectrum of prune belly syndrome

Category classification	Distinguishing characteristics
I	Oligohydramnios, pulmonary hypoplasia or pneumothorax. May have urethral obstruction or patent urachus and clubfoot
II	Typical external features. Uropathy of the full-blown syndrome but no immediate problem with survival. May have mild or unilateral renal dysplasia. May or may not develop urosepsis or gradual azotemia
III	External features may be mild or incomplete. Uropathy less severe. Stable renal function

The next group, category II, includes those infants who do not have pulmonary hypoplasia but have significant involvement of the urinary tract. This can include mild to severe renal dysplasia with potential azotemia and failure to thrive. The clinical course is one of either stabilization of renal function or progressive azotemia. Surgical intervention to tailor the urinary tract, in order to provide unimpeded drainage and decrease stasis, has been successfully performed. The impact of surgical intervention on long-term renal function remains a source of continued controversy.[17,21,91]

Category III patients with prune belly syndrome are associated with the external abdominal features and undescended testes but neither pulmonary nor renal function is severely impaired. They constitute the majority of patients with prune belly syndrome.[30,88] Although these infants may have severe dilatation of the urinary tract, they have stable renal function and usually do not require reconstructive urologic surgery.[31]

Clinical features

Genitourinary manifestations

Kidneys

Renal dysplasia and hydronephrosis are the common characteristics of the upper urinary tract in prune belly syndrome. Both grossly and radiographically, cystic dilatation of the calices and renal pelvis is present. Infundibular narrowing without obstruction and occasional ureteropelvic junction obstruction may be evident.[21] Wide variations may exist in individual renal unit appearance, function, location, and rotation (Figure 64.4).[56]

Prognosis is directly related to renal function and the degree of renal dysplasia. Stephens proposed pathogenic mechanisms to explain the development of renal dysplasia. These include (1) defects of the ureteric bud or its branches, (2) qualitative or quantitative deficiencies of the nephrogenic mesenchyme, and (3) vascular ischemic insults with resultant ureteric obstruction and renal cystic dysplasia. He suggested that the renal dysplasia of the prune belly syndrome is due to a combination of a ureteric bud and metanephric defect.[66]

The most severe degree of renal dysplasia is recognized from autopsy studies and associated with both Potter's type II and IV renal cystic changes.[56,78] These patients have associated distal outlet obstruction (urethral atresia) with a non-patent urachus, and they are usually stillborn. The kidneys are small, with disorganized histologic features consistent with dysplasia, and are most likely injured at the stage of ampullary development prior to significant nephron formation.[54]

In contrast, some patients have hydronephrosis but adequate renal function (Figure 64.5). The degree of hydronephrosis may not correlate with the ureteral dilatation or the abdominal wall deficiency. The renal parenchyma is often well preserved despite a grossly abnormal drainage system. Urinary infection rather than obstruction represents the greatest threat to the renal parenchyma. The dilatation is attributed to the mesenchymal defect and deficient smooth muscle, not to obstruction. Consequently, some resolution in the degree of dilatation can occur spontaneously in follow-up.

Ureters

The ureters are elongated, tortuous, and dilated, representing the radiographic hallmark of the syndrome (Figure 64.6).[92] The lower one-third of the ureter is more profoundly affected than the proximal portion and occupies the flared-out flanks of the abdomen. Although fluoroscopic studies demonstrate ineffective peristalsis over its entire length, true obstructive lesions of the ureter are the exception. However, pleat-like valves at the ureterovesical junction (UVJ) have been documented in two cases.[93]

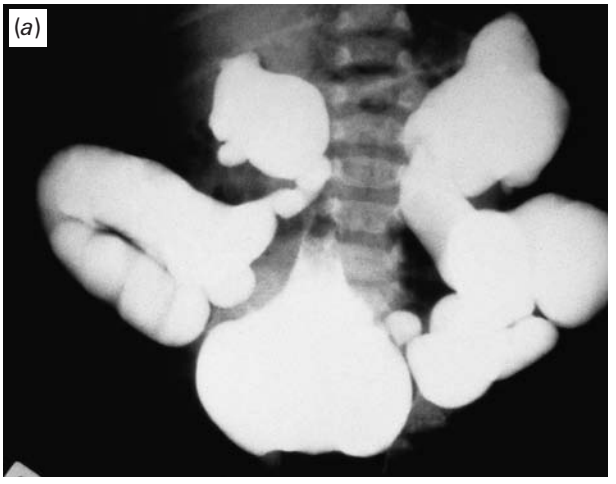

Figure 64.4 (*a*) Retrograde cystogram demonstrates the dilated, tortuous, refluxing ureters; enlarged, floppy, renal pelvis; and distended bladder, with urachal remnant. (*b*) Retrograde cystogram demonstrates vesicoureteral reflux into a dilated, dysmorphic ureter. Renal pelvis indicative of pseudoureteropelvic junction obstruction. (*c*) Same patient as (*b*) with entire left ureter and renal pelvis visualization.

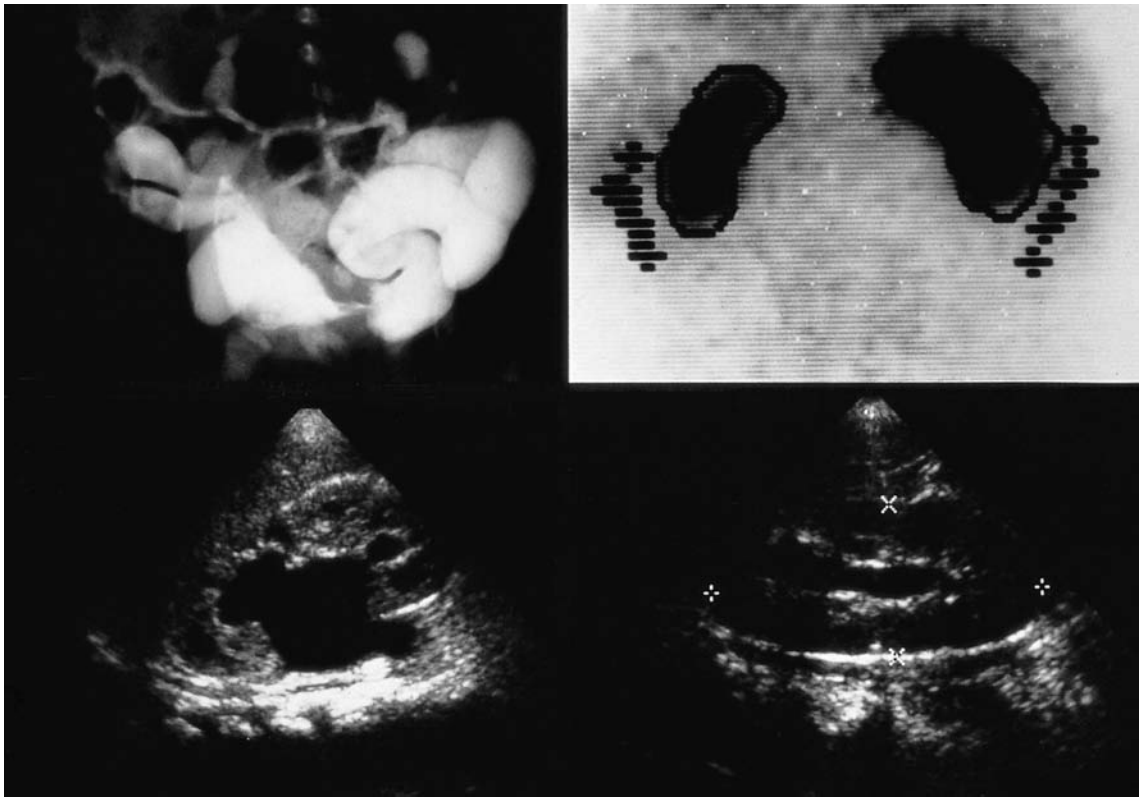

Figure 64.5 Intravenous pyelogram, DMSA renal scan, and renal sonogram of a 1-year-old child with prune belly syndrome. Despite gross dilatation and dysmorphic features of the renal pelvis and ureters, the renal scan and renal function were remarkably normal. The renal sonogram demonstrates evidence of hydronephrosis with preserved renal parenchyma.

Vesicoureteral reflux is seen in up to 85% of patients. The conventional system of grading reflux is difficult to apply, due to the dysmorphic features of the ureter, renal pelvis, and calices.[29]

Histologic examination of the ureter demonstrates a profound alteration in the content and architecture of the ureteral wall. The hypertrophy and hyperplasia of the smooth muscle cells seen in dilated ureters due to obstruction or vesicoureteral reflux are absent in the prune belly syndrome. A diffuse increase in the connective tissue with replacement of the smooth muscle is present. The ratio of collagen to smooth muscle, especially in refluxing ureters, is markedly elevated.[94] There is no differentiation into longitudinal and circular muscle layers. The patchy distribution of smooth muscle is present in both the dilated and narrowed ureteral segments. The upper ureter has more smooth muscle cells than the lower portion.[5,79] A marked decrease in the number of nerve plexuses, with degeneration of non-myelinated Schwann fibers, has been reported. This may contribute to the poor ureteral peristalsis even after corrective surgery.[95] Ultrastructural examination of the smooth muscle cells of the ureter reveals a decrease in the number of thick and thin myofilaments, which contributes to poor muscle cell performance.[79,96] The histologic and pathologic features are important to remember during genitourinary reconstructive efforts. Because the upper ureter is potentially the best, its future should not be risked by using it for temporary cutaneous diversion. The dilatation and ineffective peristalsis of the ureters result in urinary stasis and a heightened risk of infection.

Bladder

The bladder is thick walled and grossly enlarged, but trabeculations are usually absent (Figure 64.7). The normal bladder contour is deviated by a pseudodiverticulum, consisting of the urachal remnant and giving the bladder an hourglass configuration. A patent urachus may be present, especially in association with

Figure 64.6 Voiding cystourethrogram of a 1-year-old child with prune belly syndrome exhibiting the classic elongated, tortuous, and dilated ureter representing one of the radiographic hallmarks of the syndrome. The large, distended bladder is thick walled. (Courtesy of George W Kaplan MD.)

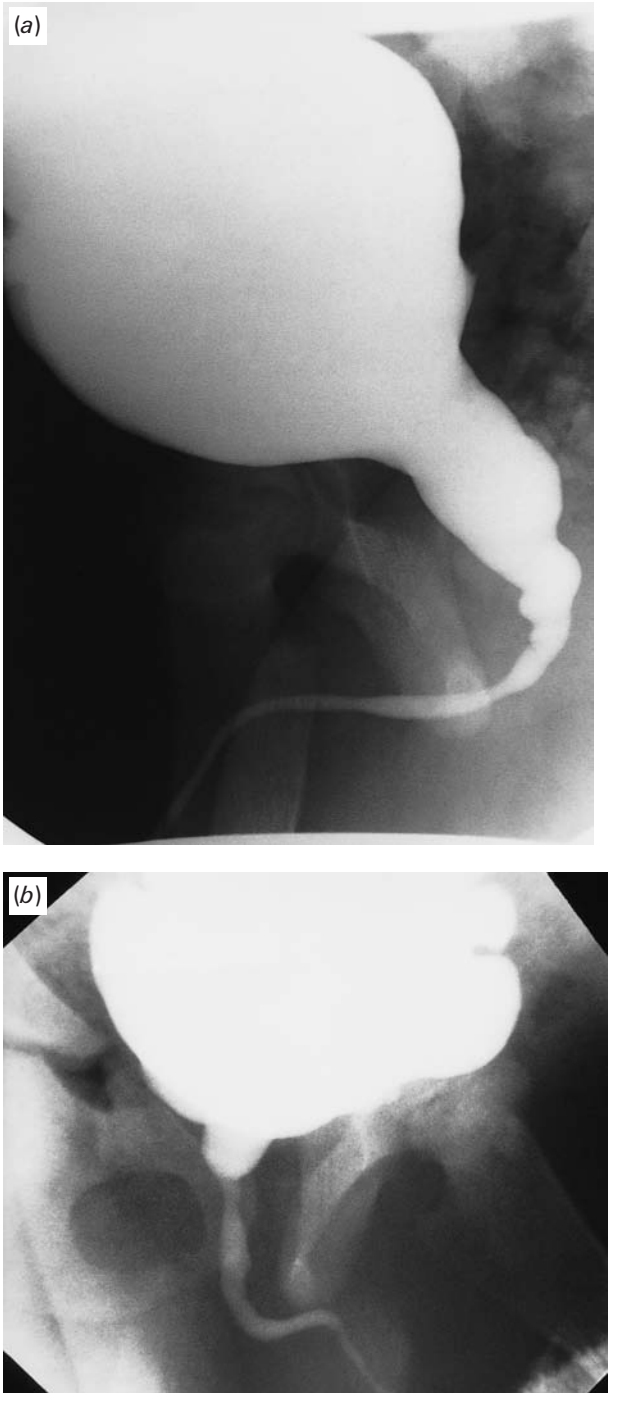

Figure 64.7 (*a* and *b*) The voiding cystourethrograms detail the grossly enlarged, but non-trabeculated bladder. The bladder neck is widely patent, with dilatation of the posterior urethra. No valves or stenosis is present.

urethral atresia or microurethra. The trigone is splayed and the ureteric orifices are located laterally, which explains the common association with vesicoureteral reflux.[66] The bladder neck is characteristically quite wide at its junction with the prostatic urethra.

Histologic evaluation of the bladder demonstrates an alteration in the ratio of connective tissue to smooth muscle. The extent of involvement is less than the ureter, and smooth muscle hypertrophy can be present.[56,97] The increased bladder thickness is largely due to fibrocytes and collagen. The anatomic innervation of the bladder is normal. No abnormality in the distribution of ganglion cells is present.[5,24]

The bladder in prune belly syndrome has efficient low-pressure storage and good compliance. However, its ability to empty is compromised by vesicoureteral reflux and poor contractility.

Urodynamic assessment of the bladder has demonstrated normal balanced voiding in some patients regardless of the gross anatomic and radiologic features.[5] Three distinct patterns of voiding have been observed: normal, prolonged voiding with a low peak, and an intermittent pattern. The voiding pattern did not correlate with residual urine volume.[98]

Maximum urinary flow rates and voiding pressures can be within normal limits for age. The filling phase of the cystometrogram is shifted to the right, with a markedly delayed first sensation to void. Bladder instability with uninhibited contractions is infrequent and usually not the explanation for urinary incontinence.[23,85,98] In those patients with unbalanced voiding manifested by urinary incontinence, an increase in residual urine with a decreased flow rate may be noted. Changes in voiding efficiency are not unusual and mandate the need for regular urodynamic assessment. Surgical intervention or intermittent self-catheterization may be necessary.

Prostate and posterior urethra

The radiographic appearance of the prostatic urethra is quite distinctive. The bladder neck is open and the posterior urethra is dilated, elongated, and tapered at the membranous urethra (Figures 64.7 and 64.8). The anterior wall of the prostate is shorter than the posterior wall. It frequently has a localized sacculation, which represents a utricular diverticulum. Reflux into the vas deferens may be present and the verumontanum is small or absent. True obstructive lesions at the junction of the prostate and membranous urethra have been described in 20% of infants, usually those with the worst prognosis. These obstructions have been described as stenosis, true valves, atresia, diaphragms, and diverticula.[52,54,56,99] A kinking of the prostatic urethra during voiding, as a result of asymmetry of its anterior and posterior walls, has been suggested as a functional obstruction in prune belly syndrome. Stephens assigned a type IV valve classification to these lesions.[57,66]

The open bladder neck and dilated prostatic/posterior urethra is evident. No urethral obstruction is present. (Courtesy of George W Kaplan MD.)

Lack of development of the epithelial portion of the prostate is a constant component of the syndrome. When compared with normal children and children with posterior urethral valves, patients with prune belly syndrome have either absent or sparsely distributed prostatic epithelial glands.[5,80,81] The prostatic hypoplasia results from an inability of the urogenital mesenchyme to induce epithelial differentiation.[81] Prostatic hypoplasia is one of the etiologies of infertility in this syndrome.[100]

Accessory male sexual organs

As with the other mesenchyme-derived genitourinary organs in the prune belly syndrome, abnormalities of the epididymis, seminal vesicles, and vas deferens have been noted. Autopsy findings have noted lack of continuity between the ductuli efferentes and rete testis. The body of the epididymis is frequently detached from the testis, a common finding with abdominal undescended testes. The vas deferens is abnormally thickened and may drain ectopically.[101] The seminal vesicles may be dilated with diverticular formation but usually are atretic or absent, which may be a diagnostic feature of prune belly syndrome.[80] All of these findings have significance in regards to the known infertility associated with prune belly syndrome.[66]

Anterior urethra

The recognized abnormalities of the anterior urethra in prune belly syndrome range from urethral atresia to fusiform megalourethra (Figure 64.9). Surviving patients with urethral atresia or microurethra have a patent urachus. It has been suggested that the microurethra is normally formed but unused and can be progressively dilated to a functional caliber.[102]

Bulbous urethral dilatation was evident in 68% of patients with prune belly syndrome.[63] Two of these patients had a fusiform megalourethra. Comparative measurements of anterior urethral diameters in patients with prune belly syndrome with normal patients have confirmed a dilated anterior urethra in prune belly syndrome patients (Figure 64.10).[103] A

Figure 64.9 A newborn with prune belly syndrome with evidence of megalourethra and penoscrotal transposition. (Courtesy of George W Kaplan MD.)

transient obstruction during fetal development at the junction of the glandular and penile urethra may explain this common radiographic finding, as well as the known association of prune belly syndrome with megalourethra.[62]

Both types of megalourethra – scaphoid and fusiform – are associated with prune belly syndrome. The fusiform megalourethra, accompanied by deficient corpora cavernosa, is a more severe defect frequently associated with renal dysplasia and lethal anomalies. Scaphoid megalourethra is characterized as a deficiency of the corpus spongiosum with normal glans and fossa navicularis. In a series of 26 patients with this anomaly, 10 had prune belly syndrome.[104] It has been suggested that the mesenchymal developmental arrest that accounts for the major features of the syndrome could also explain the urethral malformations.[63]

Testis

Bilateral cryptorchidism is an essential component of the prune belly syndrome. In the majority of patients the testes are intra-abdominal, overlying the ectatic ureters at the pelvic inlet. The epididymal abnormalities associated with abdominal undescended testis are present.[1] The intra-abdominal position of the testes

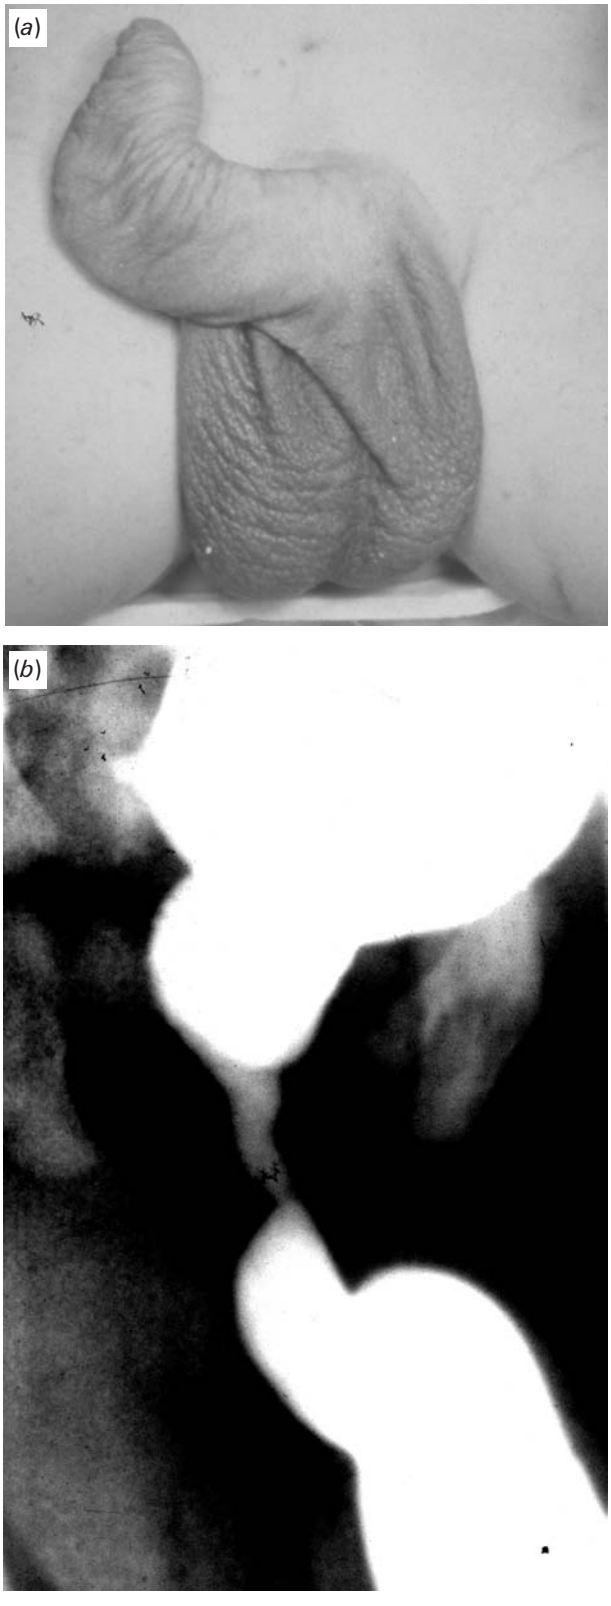

Figure 64.10 (*a*) A newborn with prune belly syndrome and megalourethra. (*b*) The voiding cystourethrogram in this patient demonstrates a large dilated bladder, open bladder neck, dilated posterior urethra, and wide, patent megalourethra. (Courtesy of George W Kaplan MD.)

predisposes these patients to increased risk of malignant degeneration of 30–50 times that of a normally descended testes.[105] At least three documented cases of testis tumor in prune belly syndrome have been reported, one of which was retroperitoneal.[3,106,107] The gubernaculum is normally attached proximally to the tail of the epididymis, travels via the inguinal canal, and attaches distally at the pubic tubercle.[66] No histologic abnormality has been noted, and the nerve supply of the gubernaculum is intact.[108]

Comparative, quantitative analysis of spermatogonia in fetuses with prune belly syndrome has demonstrated a significantly decreased number of spermatogonia and marked Leydig cell hyperplasia. These changes are evident before expected testicular descent, implying intrinsically abnormal testes.[109] Absent spermatogenesis due to prolonged intra-abdominal location has been histologically documented.[110] Azoospermia was present in adults when a semen sample was obtained.[111] Early orchidopexy is advocated for these patients to optimize potential spermatogenesis, to improve evaluation for possible malignancy, and to promote better psychological health.[29,112] With assisted reproductive techniques, specifically intracytoplasmic sperm injection (ICSI), paternity in prune belly patients is possible.[113]

The etiology of testicular maldescent in prune belly syndrome is multifactorial. Mechanical obstruction by the enlarged bladder is contributory, as the incidence of cryptorchidism is increased in other diseases associated with an enlarged bladder, such as posterior urethral valves.[114] The mechanical effects of the intramuscular pressure of the abdominal muscles pushing the testis toward the scrotum are obviously deficient in the prune belly syndrome. In addition, given the mesenchymal abnormalities of the syndrome, the ability of the gubernaculum to respond hormonally to guide the testes to the scrotum may be impaired.[82]

Sexual function and fertility

Woodhouse and Snyder studied sexual function in nine adult patients with prune belly syndrome. All had normal libido, with normal erections and orgasms. Seven had retrograde ejaculation. All patients studied to date have been azoospermic.[28,111] These patients all had orchidopexy performed late in childhood. Earlier orchidopexy may improve spermatogenesis, as germ cells have been demonstrated in these patients.[112]

There is no report of a patient with prune belly syndrome becoming a father naturally. However, the first reported case of paternity in a prune belly patient involved the use of ICSI and produced twins.[113] Patients with prune belly syndrome have multiple factors, other than spermatogenesis, that contribute to infertility. An open bladder neck and poorly developed prostate result in retrograde ejaculation. Associated abnormalities of the prostatic epithelium and seminal vesicles affect the amount and content of the seminal fluid. Vas deferens obstruction and epididymal abnormalities associated with maldescent affect sperm delivery and maturation.

Extragenitourinary manifestations

Abdominal wall

The wrinkled, floppy abdominal wall that characterizes the syndrome results from a deficiency of the underlying musculature. The functionally impaired abdominal wall can result in significant morbidity. These infants are unable to sit up directly from the supine position, and this delays the onset of walking.[3] The lack of mechanical assistance from the abdominal wall contributes to the noted difficulties with respiratory infections and to chronic constipation.[115] In addition, the long-term psychosocial effects of poor body image have been addressed.[30,31]

Autopsy studies have shown that the muscles most severely affected are those ventrally and laterally located. The epaxial and hypaxial trunk muscles develop normally. The order of severity of involvement from most to least involved is: transversus abdominis, rectus abdominus below the umbilicus, internal oblique, external oblique, and rectus abdominis above the umbilicus (Figure 64.11).[2,18] There is cephalic displacement of the umbilicus due to unopposed contraction of the upper rectus abdominis muscle. The diminished muscle mass, if severe, allows one to observe spontaneous contraction of the underlying bowel and easily palpate the abdominal organs and kidneys. Because the muscular deficiency may not be symmetric, a more dominant flank bulge on one side of the abdomen is often present and coincides with the dilated distal ureter (Figure 64.12).

Electromyographic studies of the abdominal wall have confirmed the anatomic findings. The lower midline musculature demonstrates the least amount of electrical activity. Recruitment of voluntary motor units is greatest in the upper lateral musculature.[116]

Autopsy studies of the abdominal wall have demonstrated normal segmental nerve distribution and normal blood supply.[56,66] The distribution of muscle fibers is haphazard. In more severe cases, the

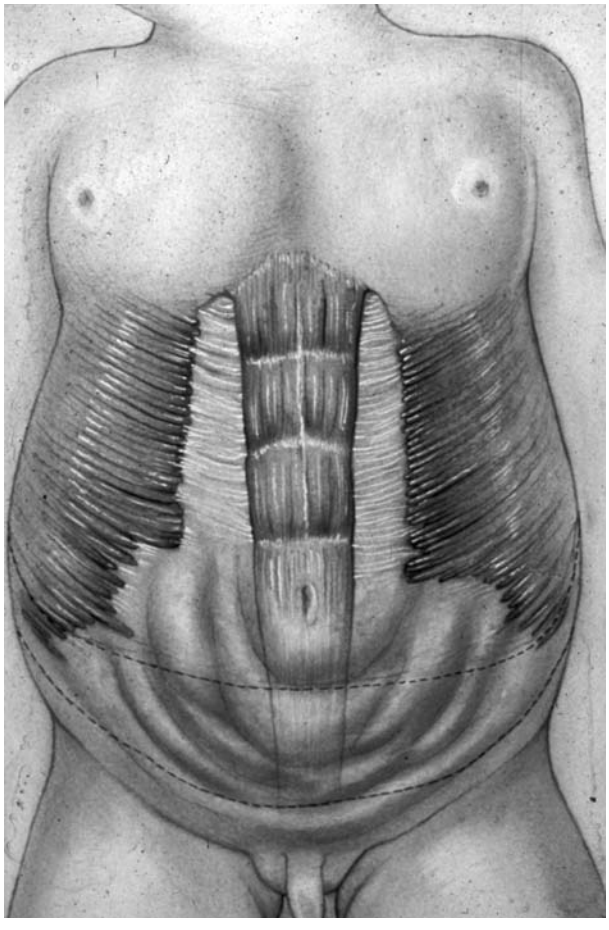

Figure 64.11 The abdominal wall deficiencies in prune belly syndrome. The epaxial and hypaxial trunk muscles develop normally. The order of severity of involvement from most to least involved is: transversus abdominis, rectus abdominis below the umbilicus, internal oblique, external oblique, and rectus abdominis above the umbilicus. (Reproduced from Randolph,[116] with permission.)

entire thickness of the abdominal wall consists of skin, connective tissue, superficial fascia, and peritoneum (Figure 64.13). In the infant there is no aponeurotic layer that might represent atrophied muscle.[23] Fortunately, the poorly developed abdominal wall heals well after incision despite the muscular layer deficiencies.

Microscopic examination demonstrates fatty infiltration interdigitated with muscle fibers. These fibers have been characterized as hypoplastic, atrophic, and hypertrophic, which adds further confusion to an apparent etiology.[65,117] Others have found the muscle cells to be clear and normal in appearance and at times associated with myotubular embryonic cells similar to that seen in the fetus of about 10 weeks' gestation.[64,66] Ultrastructural abnormalities demonstrated by electron microscopy include loss of coherence and orientation of the Z-bands, mitochondrial disruption, and clumping of glycogen granules. These changes are non-specific, but are consistent with hypoplastic histologic changes.[65]

Associated anomalies

Abnormalities of other organ systems result in long-term morbidity for as many as 75% of patients with prune belly syndrome (Table 64.3).[115] Growth was impaired in 32% of surviving patients in one large series and was poorly correlated with renal function. This impairment was most manifest in the first year of life, with subsequent stabilization but incomplete catch-up growth.[115] Developmental delay has also been documented in selected patients.

The non-urologic associated anomalies in patients with prune belly syndrome are a major source of morbidity and mortality. Care of these patients requires close cooperation with all caregivers. The urologic

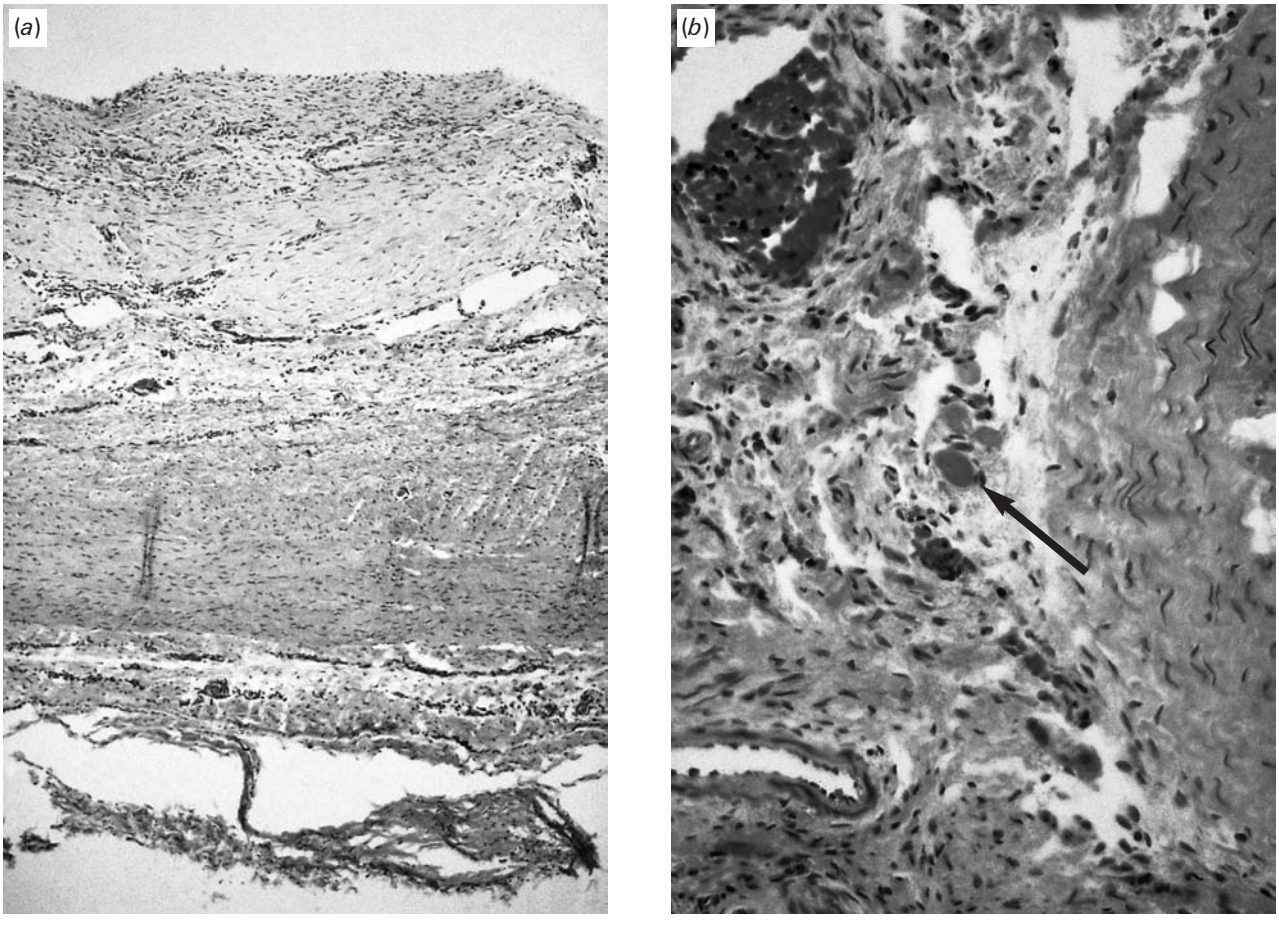

Figure 64.13 (*a*) A cross section of the abdominal wall of an infant with prune belly syndrome. Note the scant and haphazard arrangement of muscle fibers. (*b*) A high-power view of abdominal wall composed largely of collagen and fibrous tissue. The arrow points to scant skeletal muscle fibers.

manifestations of prune belly syndrome rarely require emergent treatment.

Orthopedic

Orthopedic-related problems in prune belly syndrome are present in 45–63% of cases.[118] In most series, musculoskeletal anomalies predominate, with congenital dislocation of the hips the most frequent finding. This requires early treatment and may be resistant to conventional therapy.[118] Lateral dimples of the elbows and knees are the mildest manifestation of the compression effect of intrauterine oligohydramnios (Figure 64.14). More severe deformities, attributed to oligohydramnios and intrauterine compression, are recognized usually at autopsy as lower limb deficiencies and arthrogryposis.[4,119] Talipes equinovarus, polydactyly, syndactyly, and torticollis have been reported.[24,56] Pectus carinatum and pectus excavatum deformities are frequently present. Scoliosis is the most common spinal deformity. In one instance, scoliosis was associated with thoracic segmental insensibility.[120] As prognosis improves in these patients, orthopedic interventions will play a greater role in management.

Figure 64.14 Lateral dimple of the knee in this infant with prune belly syndrome is a mild manifestation of the compression effect of intrauterine oligohydramnios.

Table 64.3 Extragenitourinary abnormalities in prune belly syndrome

Organ system	Frequency (%)	Manifestations
Pulmonary	55	Pulmonary hypoplasia Pneumothorax Pneumomediastinum Lobar atelectasis Pneumonia Chronic bronchitis
Orthopedic	45–63	Congenital dislocation of hips Chest wall deformity: Pectus excavatum Pectus carinatum Scoliosis Genu valgum Talipes equinovarus Severe leg maldevelopment: Arthrogryposis
Gastro-intestinal	30	Malrotation Intestinal atresia Intestinal stenosis Volvulus Anorectal agenesis Imperforate anus Omphalocele Gastroschisis Hepatobiliary anomalies Acquired megacolon
Cardiac	10	Patent ductus arteriosus Atrial septal defect Ventricular septal defect Tetrology of Fallot

Gastrointestinal

Gastrointestinal anomalies are present in over 30% of autopsied patients with prune belly syndrome. These anomalies are commonly recognized in the postnatal period. The majority of anomalies such as malrotation, atresia, stenosis, and volvulus are due to persistence of the embryonic wide mesentery, with absent fixation to the posterior abdominal wall.[121] This same suspension abnormality allows the spleen to wander freely in the abdominal cavity and acute splenic torsion has been reported on two occasions.[122] It has been recommended that all patients with prune belly syndrome have radiographic assessment of their alimentary tract.[121] Anorectal agenesis, imperforate anus, omphalocele, and gastroschisis have been reported in association with prune belly syndrome.[121,123–125] Chronic constipation is a frequent problem with these children, and is attributed to a decrease in abdominal wall pressure aiding evacuation. Acquired megacolon can result. Chronic constipation requires continuous attention with dietary and cathartic intervention.[12,115]

Cardiac

Cardiac anomalies have been reported in up to 10% of patients with prune belly syndrome. Patent ductus arteriosus, atrial and ventricular septal defects, and tetralogy of Fallot occur with increased frequency in prune belly syndrome.[126,127] The severity of the cardiac involvement will dictate initial care of the infant, as the urologic anomalies rarely demand immediate treatment.

Pulmonary

Pulmonary and respiratory difficulties pervade the lives of these patients from birth to adulthood. Severe pulmonary hypoplasia, with associated oligohydramnios and renal dysplasia, is incompatible with life. Initial prognosis depends upon pulmonary development. A review of most series demonstrates that approximately 20% of newborns will die in the perinatal period as a consequence of pulmonary complications.[21,28,29] Of those that survive the newborn period, clinically significant pulmonary problems were noted in 55% of patients.[115] Pneumothorax and pneumomediastinum may be present at birth, with or without pulmonary hypoplasia, and an early chest X-ray is advised. Chest wall deformities and abdominal muscle deficiency impair mechanical ventilation, which results in a ventilatory limitation and a high incidence of lobar atelectasis and pneumonia.[128,129] Chronic bronchitis and the development of respiratory insufficiency following upper respiratory infections or anesthetics are well recognized, and appropriate pulmonary support must be provided.[115,128]

Patient evaluation

Prenatal

Prenatal diagnosis of prune belly syndrome has been made as early as 11 weeks of gestation on ultrasound.[130] With improved ultrasonic capability and

surveillance protocols, the ability to diagnose major genitourinary abnormalities in the early gestational period is increased.[131] However, definite distinction from other causes of hydronephrosis, such as posterior urethral valves, can be difficult. Previous ultrasonic diagnostic accuracy varies from 30 to 85%.[132]

The development of vesicoamniotic shunt procedures makes possible in-utero treatment of patients with obstructive uropathy.[133–135] Specific criteria for in-utero intervention include normal karyotype, severe oligohydramnios, and predicted good renal function.[133,136] The timing for intervention is critical, as renal dysplasia is more pronounced with increasing gestational age. Although several reports of vesicoamniotic shunt procedures for fetal obstructive uropathy exist, reviews have failed to document a beneficial effect of fetal intervention on subsequent renal function or pulmonary development.[132,137]

Hence, prenatal intervention to relieve potential obstruction in a fetus is difficult to justify. As the majority of patients with prune belly syndrome have no demonstrable evidence of obstruction, and renal function does not correlate with the amount of dilatation present in the urinary tract, the risks and benefits of in-utero intervention must be carefully weighed.[138–140]

Newborn

The appearance of the abdominal wall leaves little doubt as to the diagnosis in the newborn. Given the wide range of disease severity, a multisystem evaluation to rule out significant cardiac, pulmonary, or other associated malformations must take place in the neonatal period.[141] An immediate chest X-ray is necessary to exclude associated pneumothorax and pneumomediastinum. The presence of severe pulmonary hypoplasia with progressive inability to oxygenate the infant immediately affects prognosis. This is usually associated with the antenatal demonstration of oligohydramnios, which indicates impaired renal function.[90]

Initial creatinine measurements reflect maternal renal function and repetitive sampling is necessary. If after 48–72 hours the serum creatinine is >1.0 mg/dl in the term infant or 1.5 mg/dl in the preterm infant, a degree of renal insufficiency is present. A progressive rise in serum creatinine over the first few weeks of life portends a poor prognosis. If initial nadir creatinine is <0.7 mg/dl, then subsequent renal failure is unlikely.[142] Urine is sent for baseline culture and antibiotic prophylaxis is initiated. Measurement of serum and urinary electrolytes at birth can be helpful in assessing sodium conservation, implying adequate renal function.[143] In the premature and full-term infant, the glomerular filtration rate (GFR) is initially low, then rapidly increases.[144] This must be remembered in relation to the administration of intravenous contrast agents, which may rapidly elevate plasma osmolality, causing intraventricular hemorrhage as well as further impairment of renal function.[145]

Diagnostic evaluation

A thorough urologic evaluation proceeds after stabilization of the patient's comorbidities. Physical examination and ultrasonography of the urinary tract are initially required. Renal sonograms provide information on cortical thickness, presence of cystic changes, and renal size. Sonographic examinations before and after voiding give a clue to the presence of vesicoureteral reflux and postvoid residual urine. Serial serum electrolyte determinations, urinalysis, and urine culture are essential.

Radiologic assessment in the newborn is tempered by the known risks of intravenous contrast and the introduction of infection with retrograde studies. Initially, a VCUG is performed in those infants with abnormal renal function to insure that a true anatomic, urethral obstruction is not present. This 'lethal variant' and the potential confusion with posterior urethral valves 'masquerading' as prune belly syndrome must be differentiated, as treatment changes dramatically.[53,146,147] In addition, the VCUG demonstrates vesicoureteral reflux in up to 85% of patients and assesses bladder emptying. All infants are treated with antibiotics prior to VCUG to decrease the risk of infection. In general, the radiologic assessment of the urinary tract is tailored by the management philosophy of the individual urologic surgeon. Contrast studies requiring risky instrumentation are avoided in those infants with good renal function.

After initial evaluation, a technetium 99m (^{99m}Tc) diethylene triaminepenta-acetic acid (DTPA) renal scan and a mercaptoacetyltriglycine (MAG3) renal scan can provide both functional and anatomic information. Blood flow, differential renal function, and drainage in response to furosemide (Lasix) can be assessed and compared with subsequent studies (Figure 64.15). The limitations of diuresis renography in demonstrating obstruction in patients with prune belly syndrome have been noted. A Whitaker test is occasionally necessary as the definitive study to

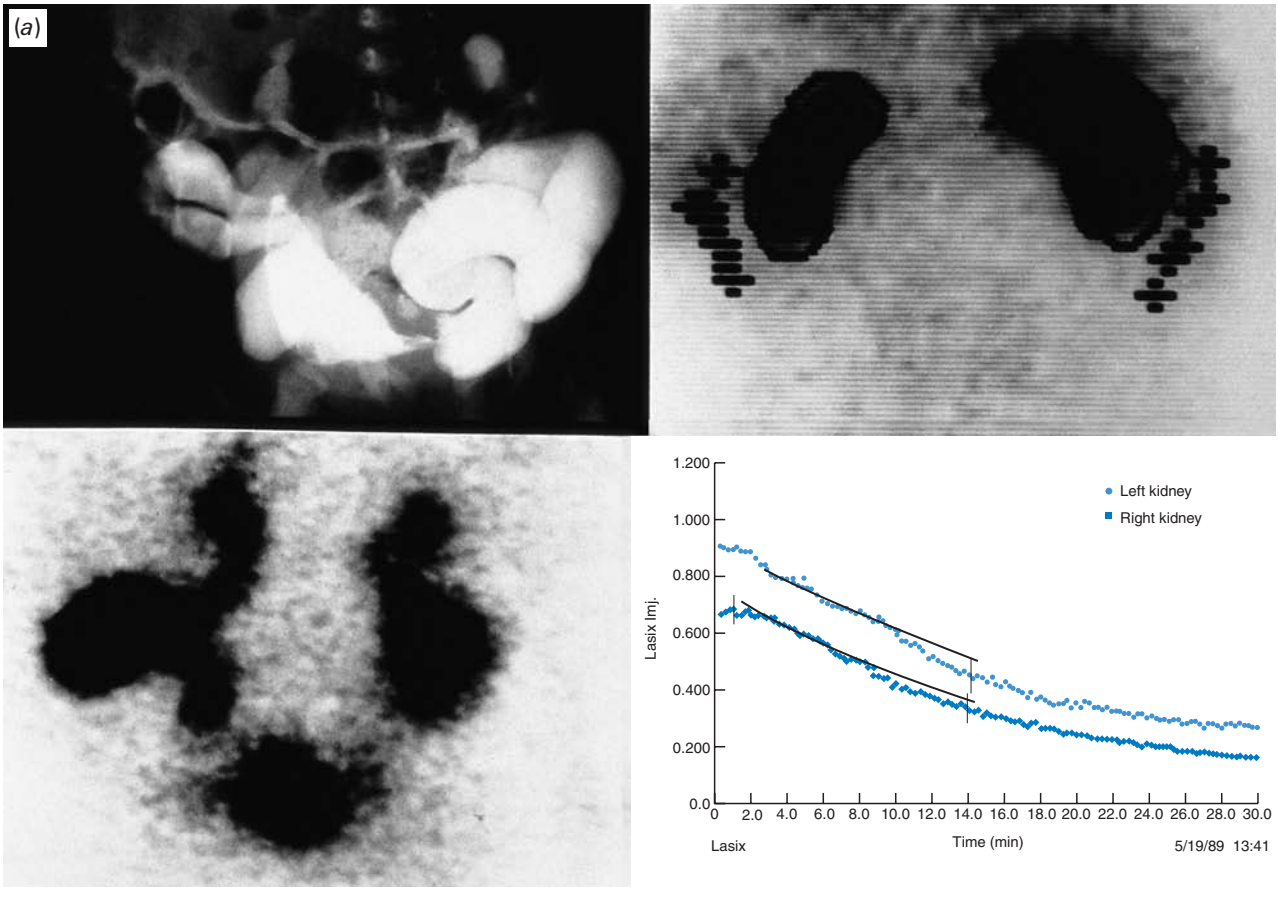

Figure 64.15 (*a*) Intravenous pyelogram and Lasix (furosemide) renal scan in a child with prune belly syndrome (top). Note the anatomic definition of the renal scan (bottom) and adequate drainage of the upper collecting system (graph). Renal function was normal.

demonstrate significant obstruction.[92] A dimercaptosuccinic (DMSA) acid renal scan is performed rather than an intravenous pyelogram (IVP) to evaluate renal size, tubular mass, and differential function. Longitudinal studies are invaluable to assess renal growth and scarring, as these patients require long-term follow-up.[148]

Patient management

The overall goals of initial management are to preserve renal function and prevent infection. The attainment of these goals is possible via a variety of therapeutic approaches, which range from watchful waiting to immediate surgical reconstruction of the urinary tract.[17,22,27]

Early surgical intervention in the neonate is avoided, unless a rising creatinine or infection intervenes, requiring early vesicostomy. Unless salvaged by extraordinary means (extracorporeal membrane oxygenation with or without dialysis), patients with category I disease associated with prenatal oligohydramnios and postnatal pulmonary hypoplasia usually die in the immediate postnatal period due to pulmonary complications. In those few infants surviving the pulmonary insult, high urinary diversion by cutaneous pyelostomy has been attempted to provide optimal urinary drainage.[91] Unfortunately, recovery of renal function is not usually possible as a result of severe underlying renal dysplasia.

Patients with category II involvement are serially monitored for infection and a decrease in renal function. These infants and children are placed on long-term prophylactic antibiotics. With documentation of infection, failure of adequate renal growth, or decreasing renal function, aggressive reconstruction of the urinary tract is pursued. To allow pulmonary maturation, surgical reconstruction is usually delayed until the infant is 3 months of age or more. Our approach involves a surgical remodeling to eliminate urinary stasis and vesicoureteral reflux, and promote optimal

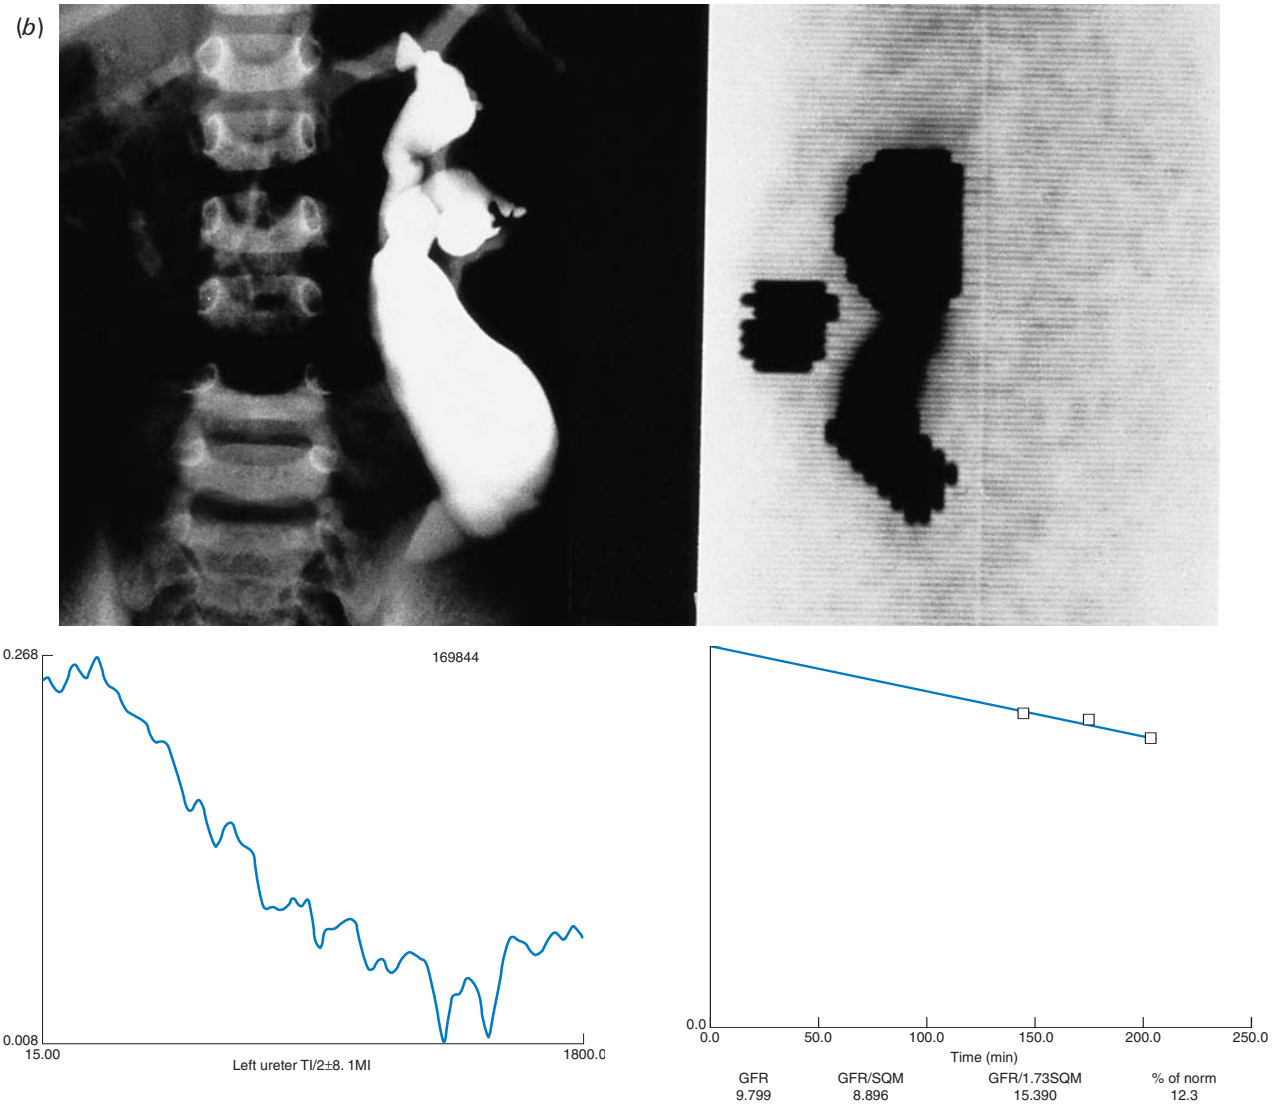

Figure 64.15 (*b*) Cystogram and Lasix renal scan with glomerular filtration rate (GFR) in a patient with poor renal function. The scan demonstrates adequate drainage, but a solitary kidney functions poorly (GFR = 15.3 ml/min/1.73 m^2).

urinary drainage (Figures 64.16 and 64.17).[22] If renal insufficiency is severe or infection is initially present, a period of urinary diversion by means of cutaneous vesicostomy is recommended.[149] Cutaneous ureterostomies probably add little to improve drainage. In addition, the upper ureter is anatomically and histologically the most normal and should be preserved if later tailored reconstruction is elected.[79,96] Combining urinary tract reconstruction, orchidopexy, and abdominoplasty at or prior to 1 year of age is our preferred approach. This optimizes the potential for improved urinary drainage, as well as addressing the issues of subsequent fertility and psychological well-being.[29]

Patients with category III prune belly syndrome demonstrate good renal function, despite gross dilatation of the upper and lower urinary tract and constitute the majority of patients. Serial assessment of renal function by selective imaging techniques is performed. Surgical intervention to reconstruct the urinary tract is not usually necessary. Antibiotic prophylaxis is recommended. Development of urinary infections or decrease in renal function mandates urodynamic assessment of the urinary tract. The demonstration of significant residual urine with unbalanced voiding warrants surgical intervention to promote emptying.[85,88] Upper tract stasis should be evaluated and a Whitaker test performed, if necessary, to rule out obstruction.[150] The results of these specific tests will help determine the type of surgical intervention. These patients benefit from early orchidopexy and

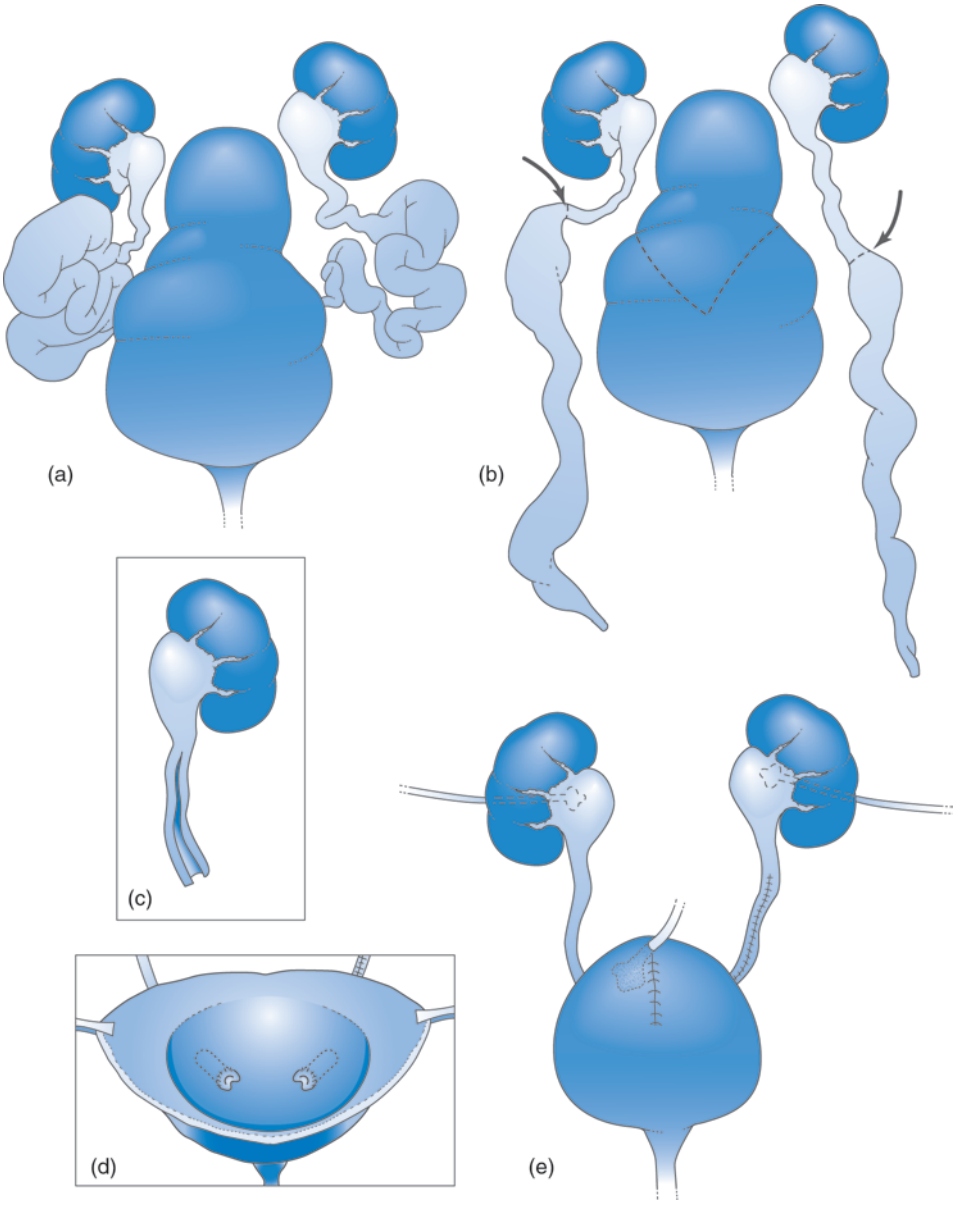

Figure 64.16 (*a–e*) Surgical technique used for extensive reconstruction of prune belly uropathy. The operation is performed transperitoneally. No attempt is made to straighten the lower ureter, inasmuch as only the upper portion of the ureter is needed for reimplantation. The ureter may require tapering. The dome of the bladder is excised (*b*; dotted line) in most patients. Ureteral stents (not shown) are used; nephrostomy tubes are rarely required.

abdominoplasty, as correction of the abdominal wall may improve defecation and voiding efficiency.[151]

Anesthetic considerations

The patient with prune belly syndrome presents unique problems to the anesthesiologist. Several reports have commented on respiratory difficulties due to the abnormal mechanics of pulmonary ventilation. The deficient abdominal musculature weakens the ability to cough effectively and predisposes these patients to postoperative atelectasis and infection.[152] In one case, prolonged, postoperative ventilation was necessary to effectively clear secretions and adequately oxygenate the patient.[153] In a review of 36 patients with prune belly syndrome, postoperative respiratory infection developed following eight of 133 anesthetics, all of which resolved with antibiotics and physiotherapy.[154] There were no intraoperative respiratory difficulties. Three deaths occurred in the postoperative period, one of which was partially due to pneumonia, as a result of ineffective cough.

Figure 64.17 (*a* and *b*) Intravenous pyelogram (two views) obtained postoperatively in a child with prune belly syndrome after a single, comprehensive surgical reconstruction.

All patients with prune belly syndrome require careful preoperative pulmonary assessment. An antecedent history of recurrent respiratory infections warrants aggressive physiotherapy, postural drainage, and intermittent positive pressure breathing treatments. Specific antibiotic therapy should be given.[153] Judicious use of postoperative analgesics, which may produce respiratory depression, is advised.

Operative interventions in prune belly syndrome

Vesicourethral dysfunction

Internal urethrotomy

In rare cases, an internal urethrotomy is indicated in patients with an anatomic urethral obstruction. At the junction of the prostatic and membranous urethra, a 'type 4' valve may be present. This redundancy partially obstructs the membranous urethra. A transurethral incision at the 12 o'clock position has been advised to improve voiding and decrease residual urine.[155]

Urodynamic assessment, including pressure–flow studies, in patients with prune belly syndrome may prove valuable.[5,23,85] The demonstration of residual urine with infection indicates the need for further testing. If a low flow rate is associated with significant residual urine and normal voiding pressure, then intervention to lower urethral resistance is warranted.[85] Endoscopic urethrotomy by hot or cold knife, to decrease outlet resistance, was successful in 10 of 11 cases in improving emptying.[156] Most authors that advocate minimal surgical intervention stress the need to closely monitor patients in follow-up. Assessment of lower urinary tract dynamics, routine urinary flow rates, and the amount of residual urine are monitored with follow-up. Internal urethrotomy is a potential first step to balanced voiding, but clean intermittent catheterization should be considered if the urodynamic criteria of outlet obstruction are not present.[27,85,156,157]

Vesicostomy

When the patient's condition is complicated by urinary infection or deteriorating renal function in the perinatal period, a cutaneous vesicostomy is the drainage procedure of choice.[3,158] This provides a vent that decompresses the entire urinary tract. The vesicostomy is performed through a small transverse incision midway between the umbilicus and the pubic symphysis. The rectus fascia is incised and a small amount of it and the skin removed. The dome of the bladder is mobilized and brought to the skin. The wall of the bladder is sewn to the fascia and matured to the skin. A generous stoma is advocated to prevent stomal stenosis.[92] A urachal diverticulum can be excised, if present. The vesicostomy can serve as an initial temporary drainage procedure prior to more extensive reconstruction.[159] A potential disadvantage is ineffective drainage of the redundant, tortuous, upper ureters or an associated ureteropelvic junction obstruction. These are unlikely, as true supravesical obstruction is rarely a component of prune belly syndrome.

Reduction cystoplasty

Reduction cystoplasty has been suggested in order to reduce volume and improve emptying.[97] Bladder volumes in excess of 3 L have been recorded in children with prune belly syndrome.[85] Concomitant removal of a dilated urachal diverticulum, which contributes to inefficient voiding, is performed. According to the law of LaPlace, a spherical shape of the bladder should allow maximal intravesical pressure with each detrusor contraction. A variety of techniques to reduce bladder volume and produce a more efficient spherical shape have been proposed.[32,97,160] A vest-over-pants closure of the bladder wall after removal of bladder epithelial strips or simple resection and watertight closure have been performed in the majority of cases.

Reduction cystoplasty has clinically resulted in fewer hospitalizations for urinary infections and initially improved voiding. However, the long-term bladder capacity and voiding efficiency were not improved.[161] Comparison of urodynamic voiding parameters between reconstructed voiding patients and non-reconstructed voiding patients did not show significant differences. Consequently, some authors do not recommend reduction cystoplasty in light of the effective and safe application of clean intermittent catheterization, except for the removal of a urachal pseudodiverticulum.[92,157]

Anterior urethra

Prune belly syndrome is associated with microurethra and megalourethra. Utilization of the unused 'micro' anterior urethra is advocated. Successful progressive soft dilatation of the urethra with normal voiding has been reported.[102] If the anterior urethra is not usable, urethroplasty techniques combining skin flaps and grafts are necessary to bridge the anterior urethral defect. Megalourethra can be repaired by application of hypospadias operative techniques.

Upper urinary tract

Vesicoureteral dysfunction

Vesicoureteral dysfunction is manifested most commonly as vesicoureteral reflux, occurring in up to 85% of patients. Ureteral valves and ureterovesical junction obstruction have been described.[93] Both conditions potentially contribute to urinary stasis and increased risk of infection. The indications for surgical correction of obstructing lesions should be based on the demonstration of decreasing renal function, infection, or a positive Whitaker test.

Surgery to repair vesicoureteral reflux has been contested because of the poor peristaltic activity of the ureters and their dissipation of voiding pressure due to increased capacity.[3] Observation of prune belly patients who remain infection free on prophylactic antibiotics has confirmed preservation of renal function.[26,88] When urinary infection becomes problematic, correction of reflux and reduction of urinary stasis become necessary. Formal tapering and reimplantation, as well as ureteral imbrication, have been used as part of the comprehensive approach to management.[29] We found no difference in the complication rate with either procedure, and 9 of 13 patients had successful elimination of their reflux. Ureteral imbrication may produce fewer problems with stenosis.[3] However, the imbricated ureter is very bulky and requires a long, wide subepithelial tunnel for reimplantation.

Temporary diversion of the upper tract by pyelostomy or ureterostomy is rarely necessary. Vesicostomy is preferred, but in those neonates with unresponsive urosepsis, high diversion to optimize drainage may be required.

Comprehensive reconstruction

Comprehensive recontruction in the prune belly patient involves reduction cystoplasty, resection of the

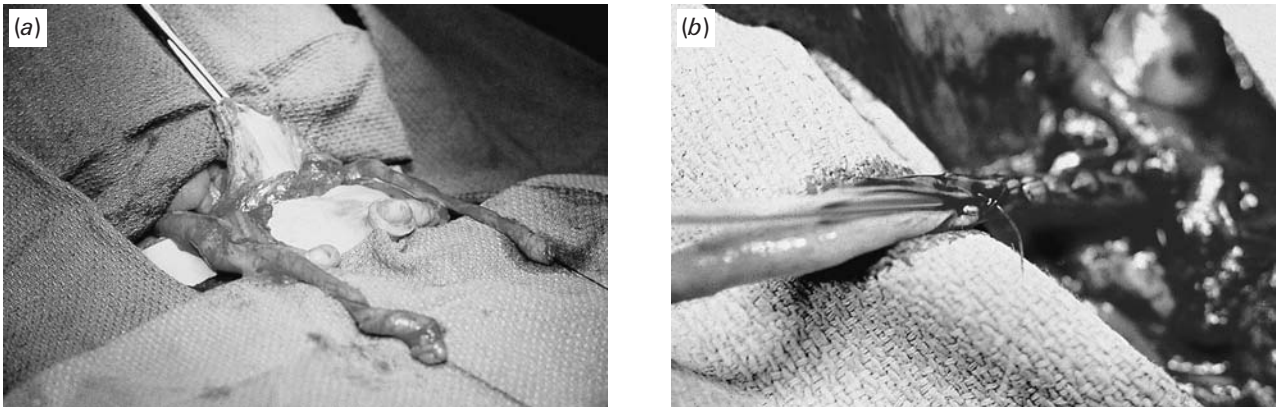

Figure 64.18 (*a*) Both ureters have been mobilized prior to reimplantation and tapering. (*b*) The ureter is closed in two layers with a running, locking suture.

distal ureter, and bilateral ureteral tapered reimplantation (see Figure 64.16). Reconstruction may be combined with the performance of the abdominoplasty and bilateral orchidopexy, usually prior to 2 years of age.[22,30] This aggressive approach was utilized in 15 patients in our series. Serial measurements of creatinine up to 13 years later documented preservation of renal function.[29] Vesicoureteral reflux was corrected in 9 of 13 patients and improved in three patients. Because of the known urinary stasis that occurs in these children, all are maintained on antibiotic prophylaxis. Therefore, our ability to decrease urinary infection cannot be totally attributed to the surgical result.

Complete surgical reconstruction, as reported by Denes et al, involved abdominoplasty, urinary tract reconstruction, and orchiopexy in a select group of 32 patients. A morbidity rate of 18.7% and a reoperation rate of 15.6% was reported. Thirty of 32 patients demonstrated stable or improved renal function at a mean follow-up of 5 years.[162]

Our proposed surgical approach is similar to that proposed by Woodward (see Figure 64.16). A wide lower abdominal incision is made that extends from the tip of the 12th rib, along the anterior superior iliac spine to the pubis and then curves upward to the opposite 12th rib.[116] This tends to spare the segmental nerve and vascular supply of the abdominal wall left for reconstruction. In addition, at the time of excision of the redundant abdominal wall, that portion with the most muscle fibers is preserved. The exposure of the urinary tract provided with this incision is exceptional and plays a role in our decision to reconstruct the urinary tract.

The posterior peritoneum is incised along the length of the ureters. The spermatic vessels are mobilized distally, care being taken not to compromise the peritoneal attachments of the vas deferens if a Fowler–Stephens orchidopexy is required. The bladder is opened in the midline with cautery. The laterally placed ureteral orifices are recognized and each ureter is mobilized. The extreme length of the mobilized ureters allows for resection of its distal third, usually the most abnormal portion. Formal tapering or imbrication is performed (Figure 64.18).[163,164] The ureters are then reimplanted, using a transtrigonal or Politano–Leadbetter technique. Stenting of the operated ureters is performed and these are brought out through the bladder and separate abdominal incisions.

Prior to reduction cystoplasty, the testes are mobilized with a wide apron of posterior peritoneum (Figure 64.19). If the reconstruction is performed prior to 2 years of age, a standard orchidopexy with intact spermatic vessels can be performed in 80% of cases.[21,29] Otherwise, a delayed or formal Fowler–Stephens orchidopexy will be necessary.[165]

The bladder is reduced in size by resection of the urachal remnant and the huge bladder dome. A strip of bladder epithelium can be removed from one of the lateral walls and closed by the vest-over-pants technique. The bladder is drained with a Malecot catheter. The previously mobilized testes are brought up through the distal abdominal wall at the pubic tubercle. A dartos pouch is created in the scrotum and each testis is secured in the pouch with permanent sutures.

The redundant abdominal wall is then held taut and marked in the midline and laterally at the costovertebral angles to outline the tissue to be excised (Figure 64.20).[116] Avoidance of removal of excessive amounts of abdominal wall is critical. The second line of incision parallels the previous incision. A large

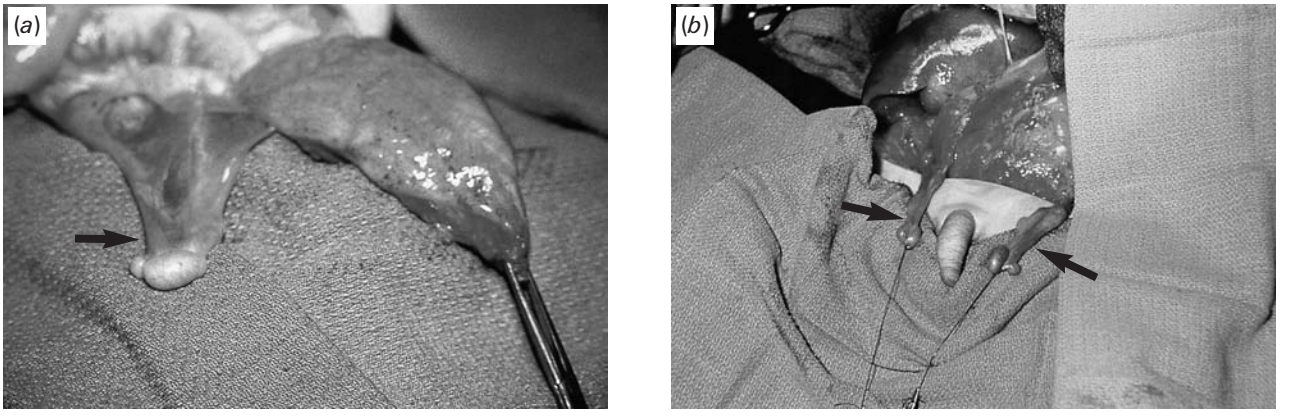

Figure 64.19 (*a*) The widely mobilized peritoneum with intact spermatic vessels (arrows) ensures good blood supply to the testis. (*b*) Achieving adequate length to secure the testes in the scrotum is usually not difficult in the child less than 2 years of age.

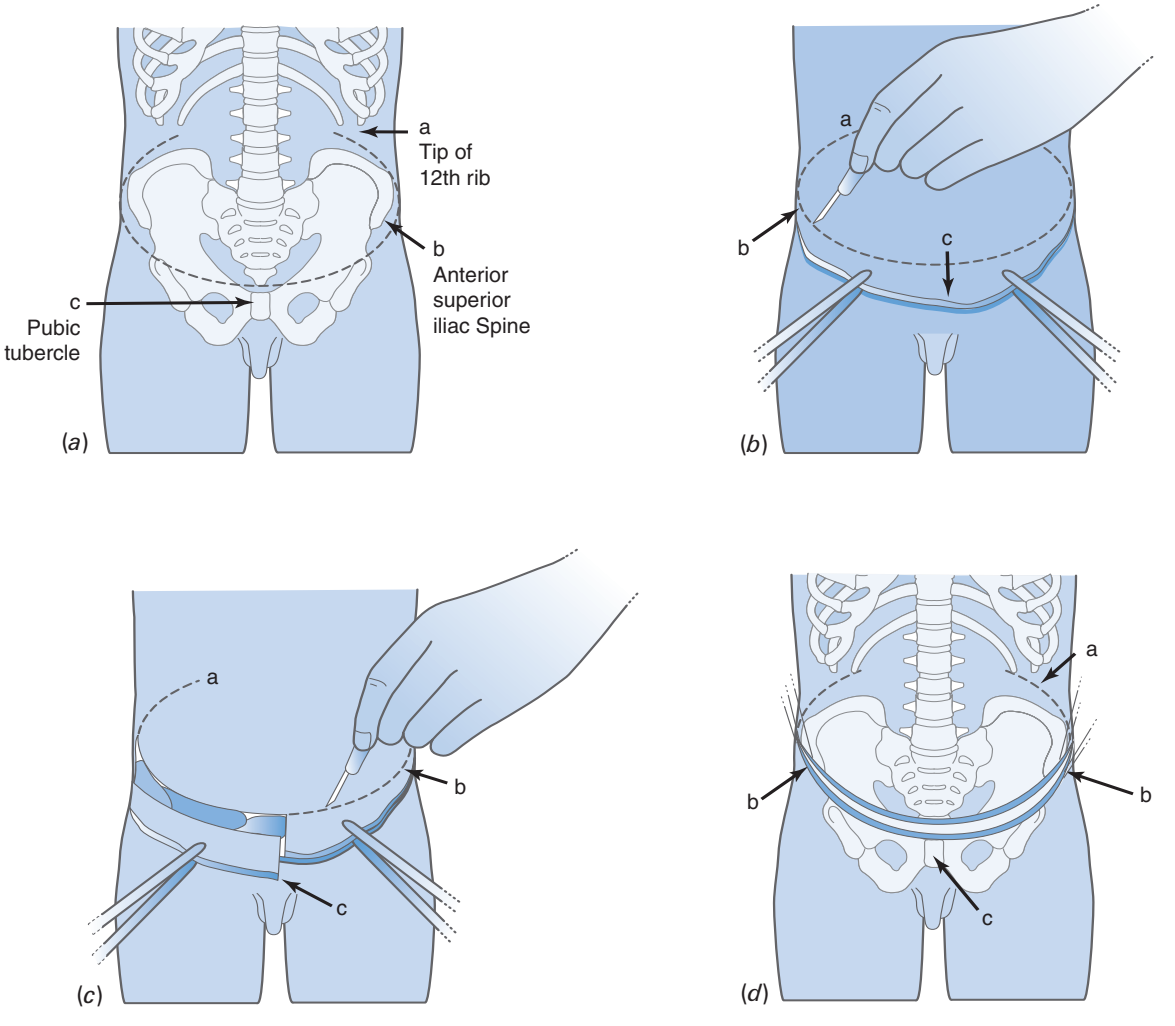

Figure 64.20 Technique of Randolph abdominoplasty. (*a*) A curvilinear incision extends from the tip of the 12th rib, along the anterior superior iliac spine to the pubic tubercle and onto the opposite 12th rib. (*b*) A parallel incision is made, avoiding removal of too much abdominal wall. (*c*) Rhomboid-like pieces of abdominal wall are removed. (*d*) Critical non-absorbable sutures are placed at the anterior iliac spines and pubic tubercle. These are placed through full thickness of the abdominal wall including the periosteum.

wedge of full-thickness abdominal wall is removed. The closure of the abdominal wall is commenced by placement of key sutures of 0 or 1–0 non-absorbable sutures at the anterior iliac spines and at each pubic tubercle. These sutures should include the periosteum of the bone and a full thickness of the proximal opposing tissue edge. The tension created occasionally allows for removal of additional lateral redundant abdominal wall. Each section between the key sutures is closed with interrupted sutures apposing the full thickness of the abdominal tissue. The subcutaneous tissue is closed to prevent dead space and the skin is approximated with a subcuticular absorbable suture.

All patients undergo preoperative enemas to clear the colon, and require good bowel decompression postoperatively. Postoperative abdominal distention must be avoided and a rectal tube placed during surgery is often valuable.

Cryptorchidism

The early correction of the cryptorchid intra-abdominal testes by a transabdominal approach is recommended to optimize spermatogenesis, facilitate examination for testicular malignancy, and improve testicular salvage. If orchidopexy is performed in the first year of life, a standard technique with preservation of the spermatic vessels can usually be performed. Orchidopexy in older children frequently requires division of the spermatic vessels, with results based on a one- or two-stage Fowler–Stevens technique.[166–168] To avoid atrophy, a broad, peritoneal pedicle mobilized with the long-looping vas, combined with early ligation of the spermatic vessels above the point of confluence of the vas and spermatic artery, is recommended.[169] Utilizing this two-stage approach, an 80–83% success rate for intra-abdominal testes has been attained.[166,167] Overall, successful orchidopexy can be expected in the majority of patients. Open and laparoscopic techniques have been described with similar results.[165,170,171] Orchiopexy can be performed at the time of comprehensive reconstruction with a high success rate.[16,21,22,29]

Microvascular testicular autotransplantation has been utilized in patients with prune belly syndrome. The spermatic vessels are anastomosed to the inferior epigastric vessels, with microsurgical vascular techniques.[172] This has normally been performed in older patients as a last salvage effort.[159] Prior to 1999, all boys with prune belly syndrome were considered infertile. However, with recent advances in male factor infertility and assisted reproductive techniques, the first assisted conception of a man with prune belly syndrome was reported.[113] Consequently, an early orchiopexy to preserve spermatogonia and testicular function in these patients is warranted.

Abdominal wall reconstruction

Abdominal wall reconstruction has a significant role in the treatment of patients with prune belly syndrome. Abdominoplasty had previously been performed to improve body image, self-esteem, and psychological well-being.[30,31] Recent studies suggest that the improved abdominal contour, with repositioning of the most functional musculature, improves voiding efficiency.[120,151] The decrease in residual urine has obvious benefit in the prevention of urinary infection. In addition, abdominoplasty was subjectively felt to improve defecation and sensation of bladder fullness.

The surgical approaches to performance of the abdominoplasty are based on preservation of the lateral and upper parts of the abdominal wall, the sites of most normal musculature. Our experience has been quite positive with the cosmetic and functional results provided by the abdominoplasty as described by Randolph et al.[116] This technique excises the most abnormal segment of redundant abdominal wall, provides excellent exposure for urinary reconstruction and orchidopexy, and preserves segmental motor nerves to the retained abdominal musculature. In 16 patients where this technique was utilized, nine had an excellent cosmetic improvement in abdominal contour, and in seven a slight protuberance remained. There were no serious complications related to the abdominoplasty procedure (Figures 64.20 and 64.21).[29] The major criticisms of this technique are that it does not improve abdominal wall thickness, and lateral bulging is not completely eliminated. However, this technique has been favored by a number of surgeons.[3,92]

The surgical approach to abdominal wall reconstruction, utilizing a midline incision with extensive subcutaneous dissection and a pants-over-vest closure has been described (Figures 64.22 and 64.23).[173,174] This technique preserves the umbilicus, uses the full thickness of abdominal wall, and provides narrowing at the waist. Excellent cosmetic results with a high degree of patient satisfaction have been reported with both the Ehrlich and Monfort techniques (Figure 64.24).[31,173–175] An adaptation utilizing an extraperitoneal plication of the abdominal wall through a midline incision decreases the extent of facial dissection,

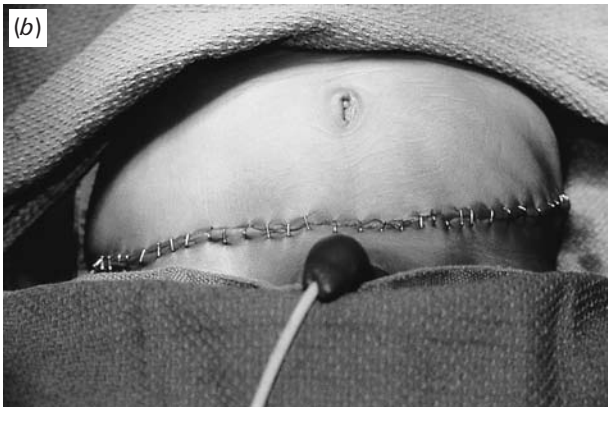

Figure 64.21 (*a*,*b*) Preoperative and immediate postoperative results of Randolph abdominoplasty. (*c*–*e*) Preoperative, postoperative, and 18 months following Randolph abdominoplasty in a 9-month-old-child.

avoids entering the peritoneal cavity and, decreases postoperative recovery time.[176] This simplification seems most appropriate for patients not requiring other concomitant surgical procedures. A modification of the Monfort abdominoplasty includes a neoumbilical modification to provide a normal anatomic placement of the umbilicus.[177]

Other treatment possibilities include abdominal binders and elasticized corsets (Figure 64.25). These aids do not address the psychological implications of

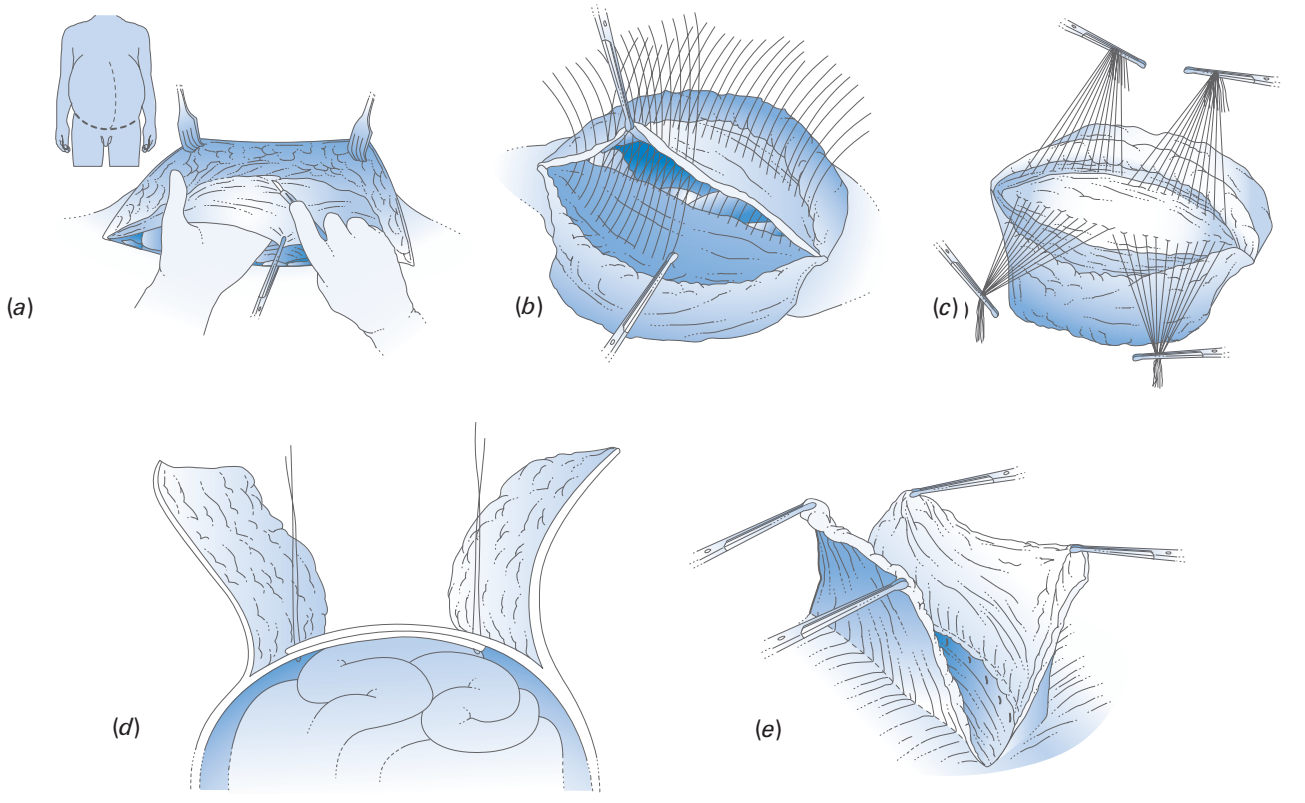

Figure 64.22 Ehrlich abdominoplasty. (*a*) Sharp dissection separates the skin and subcutaneous tissue from the musculofascial layer. (*b–d*) A 'vest-over-pants' closure of the musculofascial layers. The umbilicus can be saved on a separate pedicle. (*e*) The excess abdominal skin is removed. (Reproduced from Ehrlich et al,[173] with permission from Williams & Wilkins.)

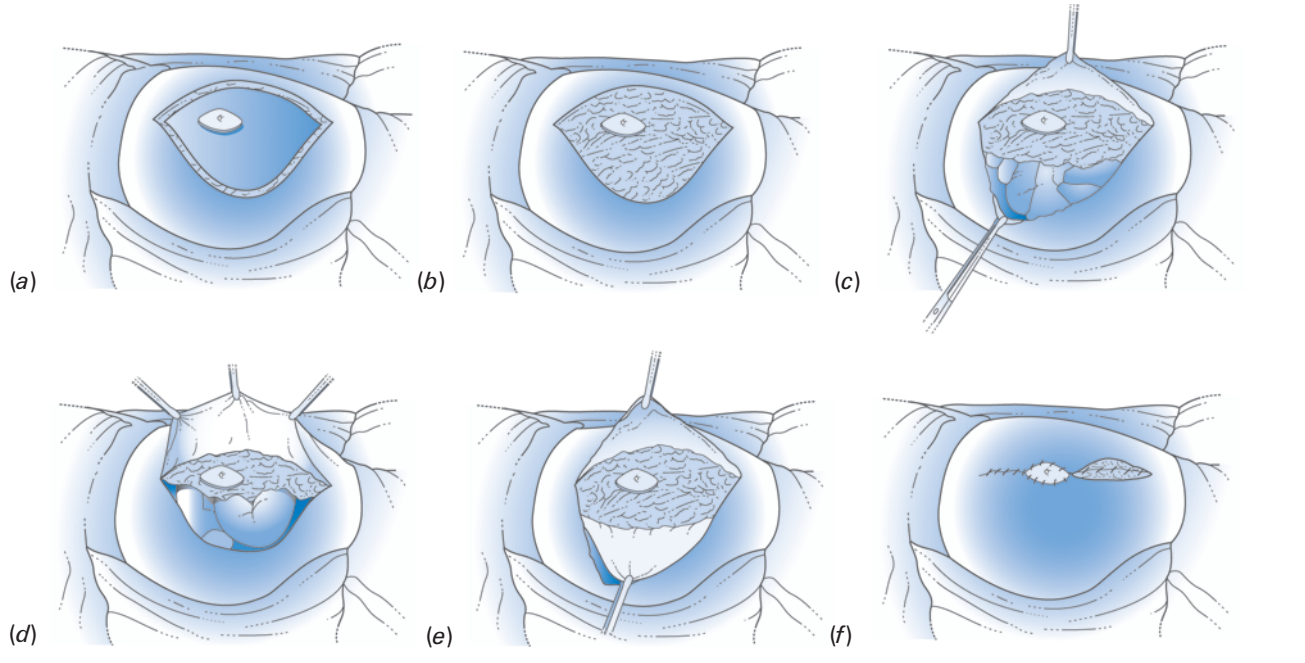

Figure 64.23 Monfort abdominoplasty. (*a*) An almond-shaped incision is made on the abdomen from the xyphoid to the pubic symphysis. (*b*) The full thickness of skin is removed, sparing the umbilicus. (*c*) The peritoneum is opened lateral to the musculofascial layer. Intra-abdominal surgery can be easily performed through these incisions. (*d*) The parietal peritoneum is incised at a level to achieve a normal-appearing waistline. (*e*) The edges of the musculofascial plate are sewn to the peritoneal incisions. (*f*) The lateral skin flaps are trimmed and sutured together in the midline. (From Monfort et al,[174] with permission from Williams & Wilkins.)

the abdominal disfigurement, which have generally been ignored in the past.[173] The importance of body image during the formative years of childhood cannot be overestimated. The abdominoplasty provides these males with freedom from abdominal binders, a more natural waisted physique, ability to wear normal pants, and participate in sports.[29]

Renal transplantation

Progressive renal insufficiency resulting from renal dysplasia, reflux nephropathy, and recurrent pyelonephritis can be successfully treated by renal transplantation. Renal transplantation in patients with prune belly syndrome was first reported in 1976.[178] The age at transplantation has ranged from 8 months to 21 years of age.[179,180] Both cadaver and living-related donor kidneys have been successfully transplanted. In a retrospective review of eight patients with prune belly syndrome who underwent transplantation, there was no statistically significant difference in patient deaths, graft survival, or graft function when compared with age-matched controls.[180] A more recent retrospective analysis of graft survival at 10 years of 47% was not statistically significantly different from age-matched controlled patients.[181] The success of renal transplantation was in part attributed to the low-pressure urine storage provided by the bladder in prune belly syndrome.[182]

Prior to transplantation, bilateral nephroureterectomies were performed in all reported cases. Radiographic and urodynamic assessment of the lower urinary tract is recommended to insure absence of obstruction and balanced voiding.[183] The use of clean intermittent catheterization to empty the decompensated bladder is not a contraindication to renal transplantation.[180,184] All patients should be kept on antibiotic prophylaxis. An unusual complication of transplantation in prune belly syndrome is allograft torsion.[185] The torsion, with resultant graft loss, is a result of lack of abdominal wall tone. Nephropexy has been recommended to avoid this disastrous complication.

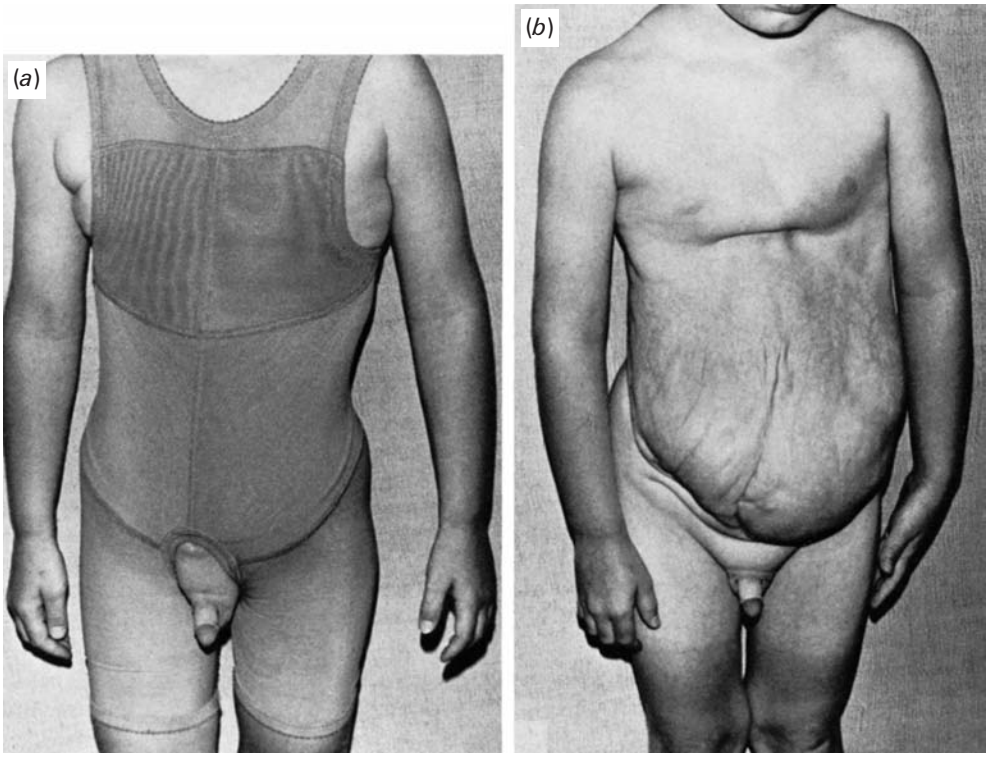

Figure 64.25 A 4-year-old boy with prune belly syndrome, (*a*) with and (*b*) without his elasticized corset.

Conclusions

The treatment of prune belly syndrome has become refined as a result of significant improvements in antibiotic therapy, diagnostic capabilities, urodynamic assessment of the urinary tract, and our understanding of the natural history of the disease. Given the wide spectrum of disease, each patient requires individualized management. When infection and stasis compromise renal growth or function, aggressive surgical intervention to promote drainage is advised. Because of the changing urodynamic condition of the lower urinary tract and its effects on renal function and urinary infection, all patients with prune belly syndrome require careful lifelong urologic surveillance.

Urethra, External Genitalia, and Retroperitoneum

Basic science of the genitalia

65

Laurence S Baskin

Introduction

Genital anomalies are the most common birth defects with the exception of cardiac malformations. Hypospadias is defined as an arrest in normal development of the urethra, foreskin, and ventral aspect of the penis; it is the most common genital anomaly, occurring in approximately 1:250 newborns or roughly 1 out of 125 live male births.[1] Hypospadias results in a wide range of abnormalities, with the urethral opening located anywhere along the shaft of the penis, within the scrotum or even in the perineum (Figure 65.1a–c). Hypospadias is also associated with ventral penile curvature (chordee). Left uncorrected, patients with severe hypospadias may need to sit down to void and tend to shun intimate relationships because of fears related to abnormal sexuality. Babies born with severe hypospadias and penile curvature may have 'ambiguous genitalia' in the newborn period, making an immediate and accurate sex assignment difficult.

Epispadias is a urethral defect on the dorsal aspect of the penis (Figure 65.1d). Epispadias is associated with a short penis, dorsal penile curvature, and, in the most severe forms, bladder exstrophy. Females (as

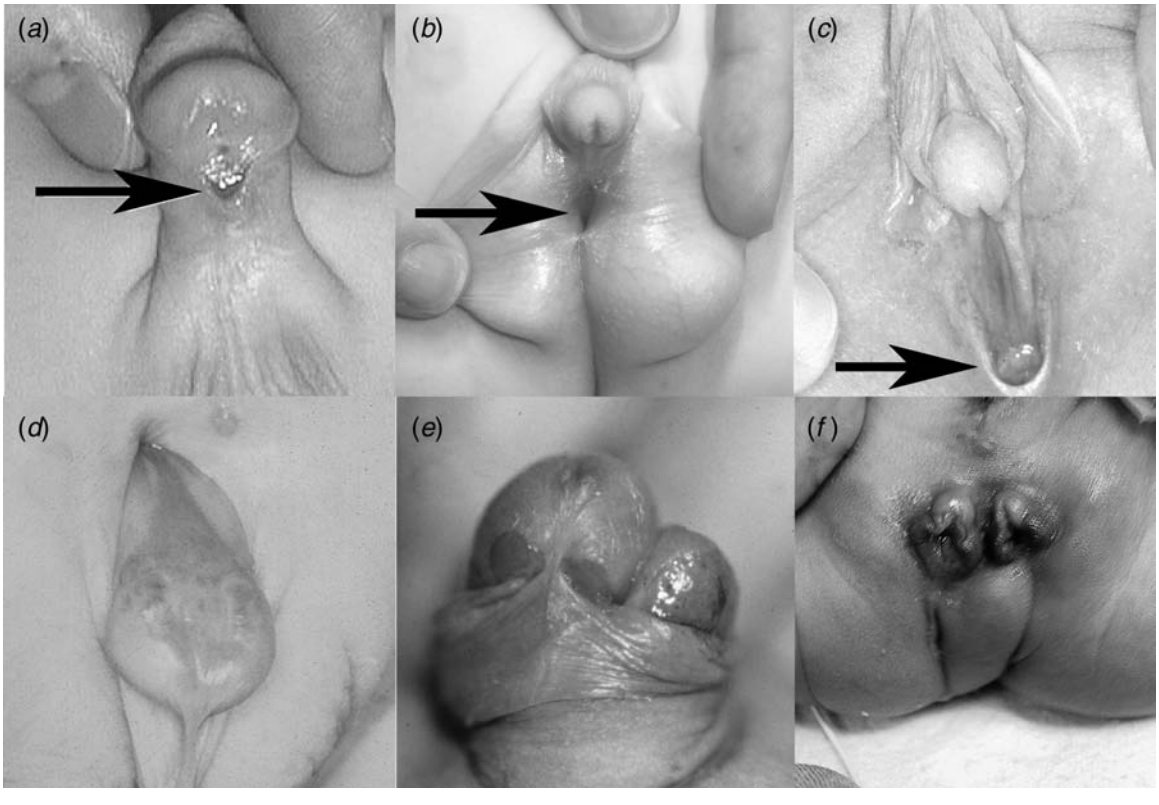

Figure 65.1 Genital abnormalities: (*a*) distal hypospadias; (*b*) scrotal hypospadias; (*c*) perineal hypospadias secondary to type II 5α-reductase deficiency; (*d*) epispadias; (*e*) penile duplication anomaly; (*f*) Complete duplication of the female external genitalia.

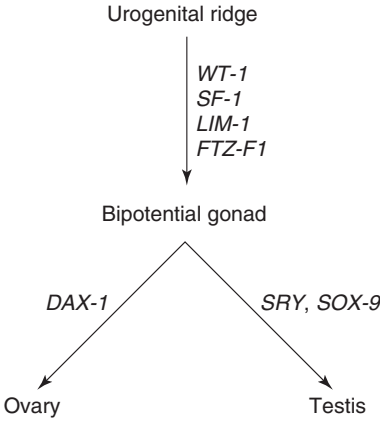

Figure 65.2 Sex-determining genes involved in testes and ovarian development.

well as males) can also suffer from these genital anomalies, and others such as genital duplication or malformations, but these problems are extremely rare (Figure 65.1e,f). To understand abnormal development of the external genitalia requires a concise knowledge of normal genital development.

Normal sexual differentiation

Chromosomal sex

The genetic material necessary for the development of the male phenotype is normally located on the short arm of the Y chromosome. The critical gene or sex-determining region on the Y chromosome is known as the *SRY* region.[2] The gene products of the *SRY* genetic cascade will subsequently direct the development of the testis by interacting with multiple other genes such as *SOX-9*. Genetic information that is necessary for male and female development beyond gonadal differentiation is located on the X chromosome and on the autosomes.

Gonadal differentiation

The gonads develop from the urogenital ridges (Figure 65.2), which are formed during the 4th week of gestation by the proliferation of the coelomic epithelium and condensation of the underlying mesenchyme along the mesonephros. The germ cells located in the endoderm of the yolk sac migrate to the genital ridges. At the early stage of development the gonad is bipotential, capable of forming into either a testis or ovary. During the 6th to 7th week of gestation, at least four different genes – Wilms' tumor suppressor gene (*WT-1*), Fushi–Tarza factor-1 (*FTZ-F1*) steroidogenic factor-1 (*SF-1*), and *LIM-1* – induce the development of the testis. The primordial germ cells differentiate into the Sertoli cells and associated Leydig cells, which aggregate into spermatogenic cords. Loose mesenchymal tissue condenses into a thick layer, the tunica albuginea, that surrounds the testis and separates it from the coelomic epithelium,

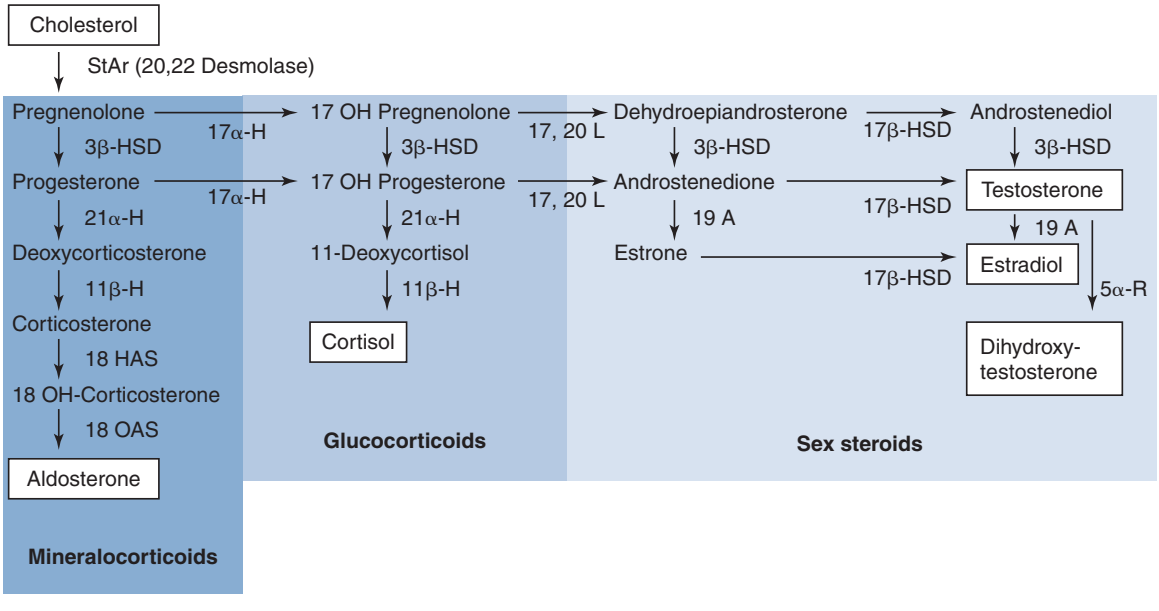

Figure 65.3 Pathway of steroid hormone biosynthesis and possible enzyme deficiencies: 3β-HSD = 3β-hydroxysteroid dehydrogenase; 17α-H = 17α-hydroxylase; 21α-H = 21α-hydroxylase; 11β-H = 11β-hydroxylase; 17, 20 L = 17, 20-lyase; 17β-HSD = 17β-hydroxysteroid dehydrogenase; 18 HAS = 18-hydroxyaldosterone synthetase; 18 OAS = 18 oxidase-aldosterone synthetase, 5α-R = 5α-reductase; 19 A = 19-aromatase.

thereby preventing further migration of mesonephric cells into the testis.

Classic teaching is that the female phenotype is the default developmental pathway in the absence of the *SRY* cascade. It is now known that at least one gene – dosage sensitive sex reversal (*DAX-1*) – is essential for ovarian development. *DAX-1* is located on the short arm of the X chromosome. The gene products of SRY and *DAX-1* compete to stimulate the steroidogenic acute regulatory protein (StAR). The StAR protein is the first step in steroidogenesis, facilitating the conversion of cholesterol to pregnenolone (Figure 65.3). In the normal XY male, *SRY* overwhelms the one functional *DAX-1* gene, stimulating testicular development and subsequent testosterone production. In the normal XX female, two *DAX-1* genes are present without the competitive SRY, down-regulating StAR and hence inhibiting testicular development, which results in ovarian development. In the fetal ovaries, the germ cells differentiate and are arrested in the last phase of meiotic prophase, forming the oocytes. The cells in the genital ridges develop into granulosa cells, which surround the oocytes and complete the formation of the ovaries.

Hormones

At 3.5 weeks' gestation, the wolffian system appears as two longitudinal ducts connecting cranially to the mesonephros and caudually draining into the urogenital sinus (Figure 65.4). At approximately the 6th week of gestation, the müllerian duct develops as an evagination in the coelomic epithelium just lateral to the wolffian duct.

During the 8th–9th week of gestation Sertoli cells of the fetal testis secrete a glycoprotein, müllerian-inhibiting substance (MIS) or anti-müllerian hormone. This protein induces the regression of the müllerian ducts through the dissolution of the basement membrane and condensation of mesenchymal cells around the müllerian duct. Because MIS acts locally, müllerian duct regression occurs only on the ipsilateral side of the fetal testis, producing this hormone. MIS also induces the formation of seminiferous tubules and further differentiation of the testis. At the 9th or 10th week of gestation, the Leydig cells appear in the testis and begin to synthesize testosterone. This hormone transforms the wolffian duct into the male genital tract, which is completed by the end of the 11th week of gestation.

Beginning in the 9th week of gestation, testosterone also induces the development of the external

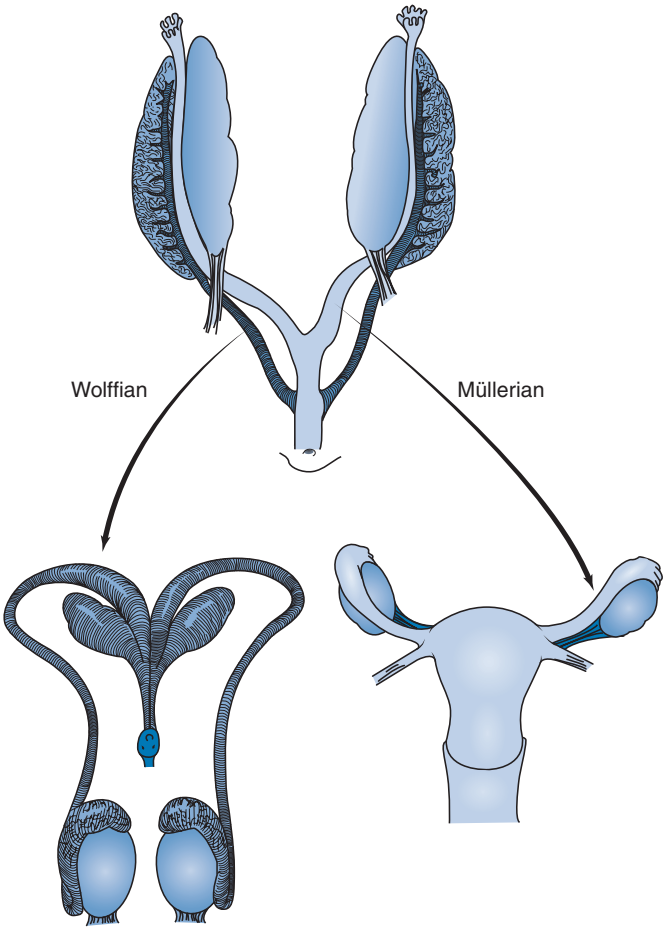

Figure 65.4 Schematic of male (wolffian) and female (müllerian) internal and external genital development from a common origin.

genitalia (Figure 65.5) from the genital tubercle, urogenital sinus, and genital swellings. At the molecular level, testosterone is converted to 5α-dihydrotestosterone (DHT) by the microsomal enzyme, type 2 5α-reductase, which is responsible for complete differentiation of the penis with a male-type urethra and glans. Testosterone dissociates from its carrier proteins in the plasma and enters cells via passive diffusion. Once in the cell, testosterone binds to the androgen receptor (AR) and induces changes in conformation, protecting it from degradation by proteolytic enzymes. This conformational change is also required for AR dimerization, DNA binding, and transcriptional activation, which are all necessary for testosterone to be expressed. Androgen binding also displaces heat shock proteins, possibly relieving constraints on receptor dimerization or DNA binding. After entering the nucleus, the AR complex then binds androgen response element DNA regulatory sequences within the androgen responsive genes and

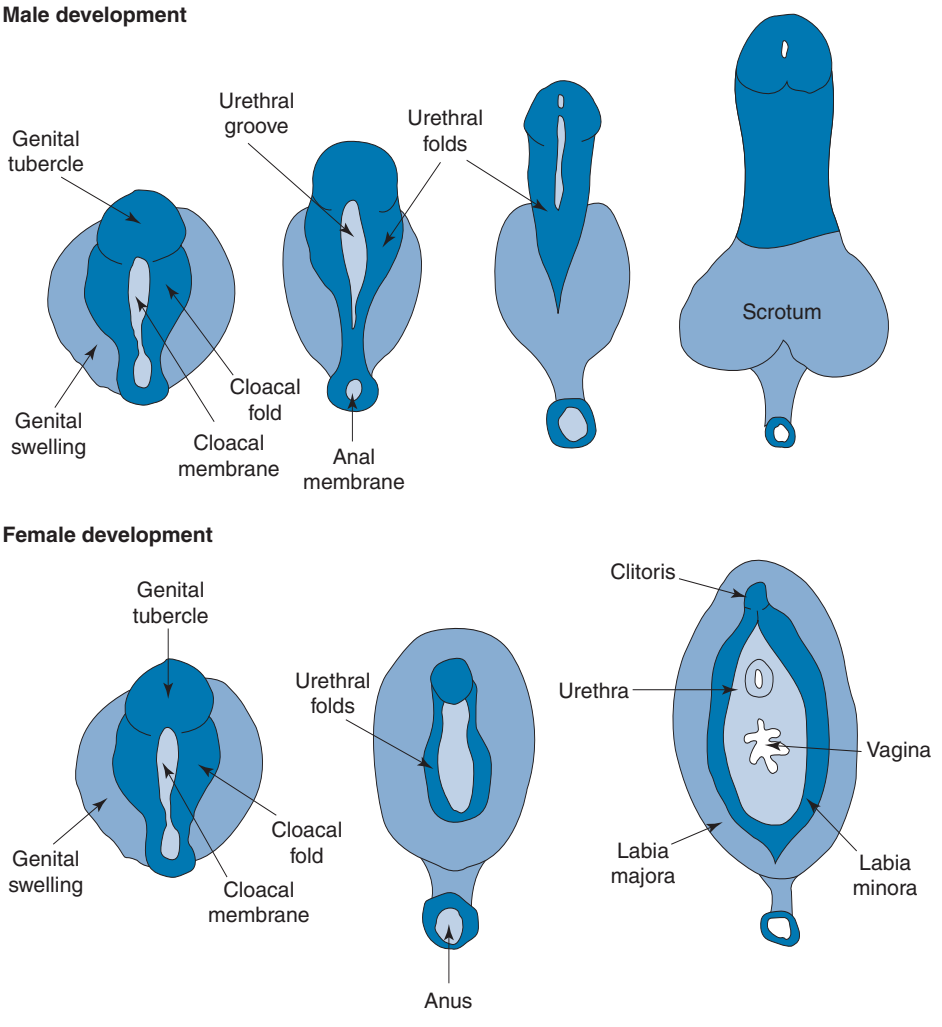

Figure 65.5 Differentiation of the male and female external genitalia from the indifferent stage to full differentiation (8–16 weeks).

activates them. DHT also binds the AR, with greater androgenic activity than testosterone, in part because of its slow dissociation rate from the AR.

DHT then binds to nuclear receptors, forming a complex that regulates the transformation of these tissues into the glans penis, penile and cavernous urethra, Cowper's glands, prostate, and scrotum. At the 28th–37th week of gestation, testicular descent into the scrotum begins. Although its mechanism is not completely understood, it is clearly an androgen-dependent-process.

The female internal genitalia develop from the müllerian ducts. Without the hormones produced by the testis, the wolffian ducts regress at the 9th week of gestation. At the same time, the müllerian ducts begin to differentiate; the cranial portions form the fallopian tubes, while the caudal portions fuse to form the uterus, cervix, and the upper portion of the vagina. Concurrently, the external genitalia, defined as the lower portion of the vagina, the vestibule, Bartholin's and Skene's glands, the clitoris, and labia minora and majora, develop from the urogenital sinus and genital tubercles. Like the testis, the ovary undergoes a partial transabdominal descent. However, transinguinal descent of the ovary does not occur, leaving the ovaries just below the rim of the true pelvis. The role of estrogen in the differentiation of the female phenotype is unclear.

Embryology: development of the male external urogenital system

Formation of the external male genitalia is a complex developmental process involving genetic programming, cell differentiation, hormonal signaling,

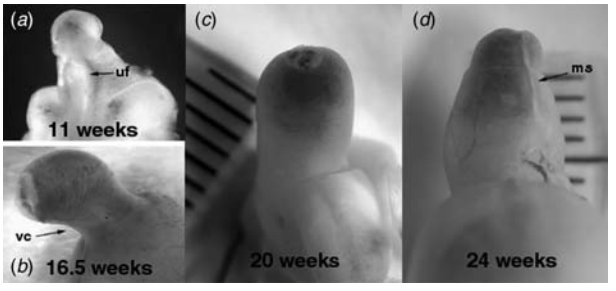

Figure 65.6 Male human fetal external genitalia during gestation. (*a*) At 11 weeks' gestation, note the urethra is open and the urethral fold (uf) and groove are prominent in the transillumination view of the phallus. (*b*) At 16.5 weeks' gestation, note the normal ventral curvature (vc) is shown and the foreskin, which is almost completely formed. (*c*) At 20 weeks' gestation, penile and urethral development looks complete, with the prepuce covering glans and the penile curvature resolving. (*d*) At 24 weeks, the prepuce covers the whole glans; note the midline seam (ms). Note the progression of natural curvature to a straight phallus during development.

enzyme activity, and tissue remodeling.[3] By the end of the 1st month of gestation, the hindgut and future urogenital system reach the ventral surface of the embryo at the cloacal membrane.[4] The cloacal membrane divides the urorectal septum into a posterior, or anal half, and an anterior half, the urogenital membrane. Three protuberances appear around the latter. The most cephalad is the genital tubercle. The other two, the genital swellings, flank the urogenital membrane on each side. Up to this point, the male and female genitalia are indistinguishable. Under the influence of testosterone in response to a surge of luteinizing hormone from the pituitary, masculinization of the external genitalia takes place (see Figure 65.5). One of the first signs of masculinization is an increase in the distance between the anus and the genital structures, followed by elongation of the phallus, formation of the penile urethra from the urethral groove, and development of the prepuce.[5,6]

At 8 weeks' gestation the external genitalia remain in the indifferent stage (see Figure 65.5). The urethral groove on the ventral surface of the phallus is between the paired urethral folds (Figure 65.6). The penile urethra forms as a result of fusion of the medial edges of the endodermal urethral folds. The ectodermal edges of the urethral groove fuse to form the median raphe. By 12 weeks the coronal sulcus separates the glans from the shaft of the penis. The urethral folds have completely fused in the midline on the ventrum of the penile shaft. During the 16th week of gestation the glandular urethra appears. The mechanism of the glandular urethral formation remains controversial. Evidence suggests two possible explanations: endodermal cellular differentiation or primary intrusion of the ectodermal tissue from the glans (Figure 65.7).

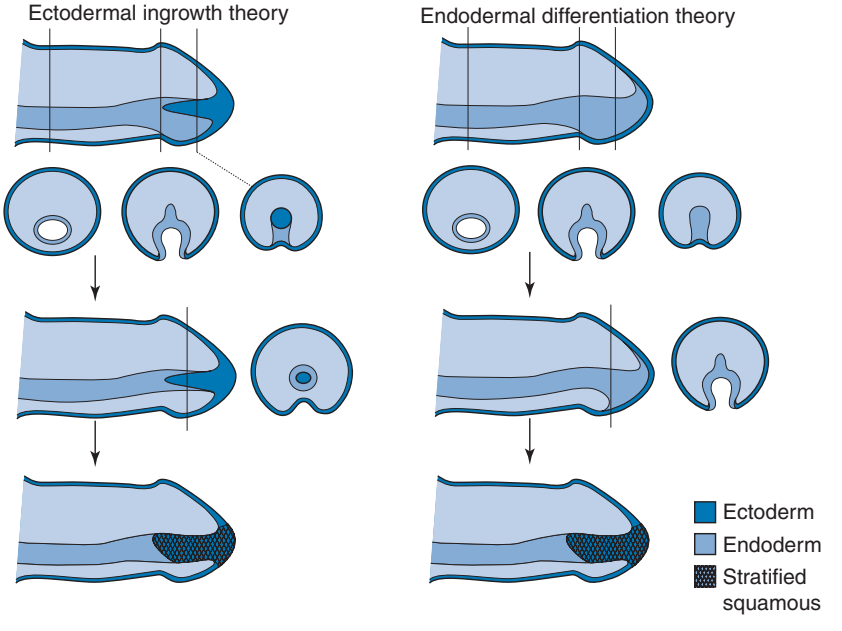

Figure 65.7 Theories of human penile urethral development. The ectodermal ingrowth theory, as described in most textbooks of embryology, postulates that the glandular urethra is formed by ingrowth of epidermis. More recent data support the formation of the entire urethra via endodermal differentiation alone.

Anatomic and immunohistochemical studies advocate the new theory of endodermal differentiation, which shows that epithelium of the entire urethra is of urogenital sinus origin.[7] The entire male urethra, including the glandular urethra, is formed by dorsal growth of the urethral plate into the genital tubercle and ventral growth and fusion of the urethral folds. Under proper mesenchymal induction, urothelium has the ability to differentiate into a stratified squamous phenotype with characteristic keratin staining, thereby explaining the cell type of the glans penis.[8] There is no evidence of an ectodermal ingrowth, as was historically proposed (old theory).[9]

The future prepuce is forming at the same time as the urethra and is dependent on normal urethral development. At about 8 weeks' gestation, low preputial folds appear on both sides of the penile shaft, which join dorsally to form a flat ridge at the proximal edge of the corona. The ridge does not entirely encircle the glans because it is blocked on the ventrum by incomplete development of the glandular urethra. Thus, the preputial fold is transported distally by active growth of the mesenchyme between it and the glandular lamella. The process continues until the preputial fold (foreskin) covers all of the glans (see Figure 65.6). The fusion is usually present at birth, but subsequent desquamation of the epithelial fusion allows the prepuce to retract. If the genital folds fail to fuse, the preputial tissues do not form ventrally; consequently, in hypospadias, preputial tissue is absent on the ventrum and is excessive dorsally.

Genital malformations

Unfortunately, to date there is no sound understanding of the etiology of genital anomalies and specifically hypospadias (which is the most common defect) that can inform primary prevention efforts and improve therapeutics. However, much is known about the genetics of hypospadias, hormone requirements for normal development, and environmental toxins, and a possible explanation for the increasing incidence of hypospadias that has already been noted.

Genetic impairment

Uncertainty about the etiology of hypospadias is in part a reflection of the complicated and incompletely understood molecular and cellular basis for normal phallus and urethral development.[10] It is well established that the urethral folds fuse during the formation of the penile urethra in the 7th–12th week after ovulation.[3] Fusion of the folds eventually leads to a fully formed penis, a process that is dependent on the synthesis of testosterone by the fetal testis. Adequate virilization of the urogenital sinus and external genitalia during embryogenesis is also dependent on the conversion of testosterone to DHT by 5α-reductase.

Increasingly, researchers are examining the role of cellular signals other than testosterone and DHT in the morphogenesis of the phallus and the etiology of hypospadias. Normal embryogenesis of the urogenital system depends on epithelial–mesenchymal interactions, and it has been hypothesized that aberrant signaling between epithelium and mesenchyme could lead to hypospadias.[8] For example, prostate development requires 'testosterone-dependent Sonic hedgehog (Shh) expression in the epithelium of the urogenital sinus'.[11] In the mouse null for Shh not only is penile development inhibited but also there is a cloacal defect.[12,13] Mice null for fibroblast growth factor 10 have a proximal urethra opening and a flattened glans consistent with the hypospadias defect.[12] It is likely that researchers may find similar genetic, signaling molecules involved in epithelial–mesenchymal interactions in the phallus that play a role in its development.

Another area of investigation with respect to the etiology of hypospadias is the expression and regulation of homeobox (*Hox*) genes. These genes are transcriptional regulators that play an essential role in directing embryonic development. Genes of the *Hox A* and *Hox D* clusters are expressed in regionalized domains along the axis of the urogenital tract. Transgenic mice with loss of function of single *Hox A* or *Hox D* genes exhibit homeotic transformations and impaired morphogenesis of the urogenital tract.[14–17] Human males with hand–foot–genital (HFG) syndrome, an autosomal dominant disorder characterized by a mutation in *HOXA13*, exhibit hypospadias of variable severity, suggesting that *HOXA13* may be important in the normal patterning of the penis.[18–20] Furthermore, recent research has shown that the embryonic expression of certain *Hox* genes is regulated by hormonal factors.[21] Estrogen and the synthetic estrogen diethylstilbestrol (DES), for example, inhibit *HOXA9*, *HOXA10*, *HOXA11*, and *HOXA13* genes in mice. Thus, in addition to defects in *Hox* genes, it is possible that improper regulation or expression of hormonal factors during embryogenesis could disrupt normal expression of *Hox* genes and lead to reproductive tract anomalies.

Hormone receptor impairment

Studies examining the androgen receptor have yielded even less insight into the etiology of hypospadias. In fact, a number of studies have concluded that defects in the AR or mutations in the AR coding sequence are rare in patients with hypospadias.[22,23] In addition, Bentvelsen et al measured AR expression in the foreskins of boys with hypospadias and age-matched controls and found no significant difference in mean AR content.[24]

Enzyme impairment

Despite the central role that testosterone plays, attempts to ascribe all hypospadias to an underlying genetic defect in this pathway have only rarely been successful. Holmes et al determined the incidence of defects in three major enzymes in the biosynthetic pathway of testosterone: 3β-hydroxysteroid dehydrogenase, 17α-hydroxylase, and 17,20-lyase (see Figure 65.3). Morning fasting serum samples of pregnenolone, progesterone, 11-deoxycorticosterone, 17-hydroxypregnenolone, 17-hydroxyprogesterone, 11-deoxycortisol, cortisol, dehydroepiandrosterone (DHEA), androstenedione, androstenediol, testosterone, and DHT were obtained.[25] No significant differences in the androgen precursors and metabolites were found between the controls and the individuals with hypospadias. The response to adrenocorticotropic hormone (ACTH) was variable, without a significant difference between the patients with different degrees of hypospadias and/or published controls. These data indicate that enzymatic defects in the steroidogenic steps from cholesterol to DHT are not a frequent etiology of hypospadias.

Environmental factors and endocrine disruptors

In the past, environmental factors were generally ruled out as causes for hypospadias.[26,27] More recently, multicausality models include environmental contaminants to determine the risk of developing a given phenotype. For example, familial clustering of hypospadias among first-degree relatives has been perceived as under the influence of a strong genetic and heritable component, but there have been many exceptions where genetics were ruled out. More recently, it has been suggested that environmental influences should be considered as well, taking into consideration that families share similar exposure: especially in those cases where the effects are the most profound, genetic predisposition exacerbated by environmental exposure should be considered.[28,29]

Attempts to determine risk factors for hypospadias have yielded a number of maternal and paternal risk factors. Among traditional studies of maternal risk factors for congenital anomalies, maternal age and primiparity are significantly associated with hypospadias, although some studies have contested the maternal age effect.[26] Paternal risk factors associated with hypospadias include abnormalities of the father's scrotum or testes[30] and low spermatozoa motility and abnormal sperm morphology.[28] It has been suggested that the recent increase in hypospadias reflects the improvement in fertility treatment, contributing to more subfertile men fathering children. As the authors state, this 'relaxed-selection hypothesis, which states that there is a redistribution in the number of children born to fertile and infertile (subfertile) couples, may account for the increasing number of other defects and cancers of male genitalia observed today and the fall in sperm counts'.[28]

In addition to parental risk factors, there is strong consensus in the literature that boys with hypospadias have lower birth weight.[31] Fredell et al examined hypospadias in discordant monozygotic twins and found that the twin with hypospadias weighed 78% of the twin without hypospadias. The birth weight difference was still significant when compared with birth weight difference between healthy monozygotic twins. Another study found that boys with hypospadias have a lower placental weight than control boys.[27] A 1995 meta-analysis of first-trimester exposure to progestins and oral contraceptives did not indicate an increased risk of hypospadias.[32] Exposure to DES was excluded in this study. However, a number of studies do list gestational exposure to progestins as a causal agent. Another recent study links a maternal vegetarian diet during pregnancy with an increase in the incidence of hypospadias.[33] This study looked at 51 boys with hypospadias from a group of 7928 boys born to mothers taking part in the Avon Longitudinal Study of Pregnancy and Childhood (ALSPAC). The authors hypothesize that vegetarians have a greater exposure to phytoestrogens than omnivores. The phytoestrogens may come in the form of soy, which is high in isoflavones, or be related to endocrine disrupters in pesticides and fertilizers.[34]

Whereas these risk factors do not reveal direct information about the etiology of hypospadias, they provide additional information that may reveal a common developmental pathway and can inform future research. For example, there is growing evidence that androgens play a central role in the lower birth weight

of girls than boys.[35] They are also crucial to the development of the male reproductive tract; thus, perhaps exposure to an agent that compromises the weight-gaining advantage of an androgen during gestation could play a role in the development of hypospadias and lowered birth weight.

Increasing rates of hypospadias have paralleled reports of other untoward endpoints related to male reproductive health, including increases in testicular cancer,[36] increasing incidence of cryptorchidism, and decreasing semen and sperm quality.[37] In another study, 8% of patients diagnosed with undescended testes (n = 252) had urogenital anomalies and over 50% of those had hypospadias.[38] The increasing incidence over the past 50 years of multiple endpoints, co-occurring with increasing production and use of synthetic chemicals, has raised concerns that environmental factors may play a role in the etiology of these problems.[29,39] It is now well documented, from wildlife studies and accompanying laboratory data, that a number of synthetic and natural chemicals commonly found in the environment can mimic or antagonize hormones or otherwise interfere with the development and function of the endocrine and reproductive systems.[40,41] Pregnant mice subjected to in-utero exposure to both estrogen and prednisone have been shown to develop hypospadias.[42] Whether endocrine disruptors are having an impact on human male reproductive health and on hypospadias in particular is difficult to determine.[43] Regardless, public health agencies worldwide are increasingly concerned about endocrine disruption and it remains an active area of research.[44–46]

Conclusion

Great strides have been made in understanding the molecular mechanism of genital formation. Understanding normal development is necessary to elucidate the etiology of abnormalities such as hypospadias. Recent work suggests that environmental exposure to endocrine disruptors may account for the increase in incidence of hypospadias cases. Prevention by reducing exposure may be the best strategy to reverse the increasing incidence of hypospadias.

Basic science of the testis

66

Julia Spencer Barthold

Introduction

Development of the mammalian gonad is an active process in both sexes that requires precise timing and coordination of diverse signaling mechanisms.[1] Although the details are not completely understood, understanding of this process has surged in recent years with routine availability of transgenic mouse models and sophisticated techniques for studying gene expression. Failure of the normal program due to delayed and/or insufficient expression of gene products may cause profound, long-term deficiencies in testicular function. It has been known for more than a decade that the sex-determining region on the Y chromosome (*SRY*) is the switch that triggers testis determination.[2] Subsequent work has identified many additional genes that participate in gonadal, testicular and/or ovarian development, the complex mechanisms involved, and the importance of cell–cell interactions in the development of cell types.[3,4] Although some species differences are apparent, knowledge of the basic mechanisms of development will aid in understanding the etiology and pathology of testicular and sexual differentiation disorders in children, such as intersex and other disorders of testicular development and descent.

Gonadal determination

Formation of the indifferent gonadal ridge anterior to the mesonephros begins at 33 days postovulation in human fetuses.[5] Germ cell migration from the extraembryonic ectoderm to the gonadal ridge is completed by about 5 weeks' gestation.[6] Expression of two genes required for gonadal determination, *WT1* (Wilms' tumor 1) and *SF1* (steroidogenic factor 1), is present by day 32 in both male and female gonads.[5] *WT1* is a transcription factor required for normal development of the urogenital ridge and for germ cell development. Homozygous deletion of *Wt1* in mice causes failure of gonadal and renal development, whereas selective deletions affecting production of specific isoforms leads to development of ovaries or dysgenic (hypoplastic, poorly differentiated, or 'dysgenetic') testes in XY fetuses[7] (Table 66.1). Therefore, *Wt1* function is critical for stabilization of the gonad but also for testis determination via expression of *SRY* and other downstream testis-determining genes. In man, *WT1* gene mutations are found in the Denys–Drash syndrome, Frazier syndrome, and WAGR syndrome (a syndrome of Wilms' tumor, aniridia, genital anomalies, and mental retardation), associated with a similar spectrum of gonadal disorders ranging from cryptorchidism and dysgenic testes without genital ambiguity to gonadal dysgenesis (streak gonads with sex reversal).[8]

Sf1, another transcription factor with similarly global effects on maintenance of the gonadal primordium, is also required for development of the adrenal, hypothalamus, and pituitary.[9] *Sf1* interacts with other key transcription factors and regulates transcription of other important genes involved in development and regulation of the reproductive tracts (Figure 66.1), including *Sry*, *Sox9* (SRY-type high-mobility group (HMG) box 9), *DAX1* (dosage-sensitive sex reversal/adrenal hypoplasia congenita critical region on chromosome X), *AMH* (anti-müllerian hormone), and *INSL3* (insulin-like 3), whose functions are discussed in more detail below. Deletion of the murine *Sf1* gene produces gonadal and adrenal agenesis in both XX and XY fetuses as well as gonadotropin deficiency.[9] In man, mutations of *SF1* cause XY gonadal dysgenesis, but are not associated with failure of adrenal or ovarian development.[10]

Homozygous deletion of patterning genes with more generalized functions during embryogenesis, including several homeodomain proteins that function as transcriptional regulators such as Emx2 (empty spiracles homolog 2),[11] Pbx1 (pre-B-cell leukemia transcription factor 1),[12] the LIM (lin-11/Islet-1/mec-3) homeobox proteins Lhx1[13] and Lhx9[14] and M33[15] (polycomb-like protein/chromobox homolog 2,

Table 66.1 Genetic regulation of gonadal development

Gene	Function	Transgenetic mouse gonadal development		
		Male	*Female*	*Clinical gonadal phenotype*
Gonadal determination				
Wt1	Transcription factor; regulator of urogenital ridge and early germ cell development	Gonadal/renal agenesis in complete knockout +KTS isoform knockout: ovaries –KTS isoform knockout: gonadal dysgenesis		Cryptorchidism, dysgenic testis, or gonadal dysgenesis
Sf1	Transcription factor; regulator of gonadal ridge and adrenal development	Gonadal and adrenal agenesis		Gonadal dysgenesis, primary adrenal failure
Emx2	Homeodomain transcription factor	Agenesis of kidneys, gonads, and reproductive tract		No gonadal pathology reported
Pbx1	Transcription factor	Agenesis of kidneys, gonads, and reproductive tract		NA
Lhx1	Homeodomain transcription factor	Gonadal/renal agenesis		NA
Lhx9	Homeodomain transcription factor; regulation of *SF1*	Gonadal agenesis		NA
M33/Cbx2	Regulation of homeotic genes	Ovaries, ovotestes or gonadal dysgenesis	Small ovaries or ovarian agenesis	NA
Pod1 (capsulin/ epicardin/ *Tcf21*)	Basic helix–loop–helix transcription factor; antagonizes *SF1*	Up-regulation of steroidogenic cells; disorganization of gonad; increased apoptosis; female phenotype in XY fetuses		NA
Igf1r/Ir/Irr	Insulin receptor tyrosine kinase signaling; cell proliferation	Ovaries in triple homozygotes Ovotestes or testes in double homozygotes	Small ovaries	NA
Gonadal development				
Sry	Transcriptional regulator; initiates testis determination	Gonadal dysgenesis	Gain of function: testis	Pure or partial gonadal dysgenesis (15–20% of cases studied)
Sox9	Transcription factor; *Sry* target; necessary and sufficient for testis determination	Ovary, gonadal dysgenesis or dysgenic testis	Gain of function: testis	Dysplastic ovary; ovotestis or dysgenic testis
Sox8	Transcription factor; functions cooperatively with *Sox9*	*Sox8*/*Sox9* double knockout more severe than *Sox9* alone	NA	NA
Gata4/*Fog2*	Transcription factor and cofactor; mediate male and female gonadal development	Gonadal dysgenesis; dysgenic testis	Abnormal ovaries	NA
Fgf9	Fibroblast growth factor receptor (FGFR2) signaling; Sertoli cell proliferation	Ovary; gonadal dysgenesis or dysgenic testis	Normal ovaries	NA

Table 66.1 *continued*

Gene	Function	Transgenetic mouse gonadal development		
		Male	*Female*	*Clinical gonadal phenotype*
Pdgfrα	Growth factor receptor; mesonephric cell migration and Leydig cell differentiation	Disorganization of testis cords; no Leydig cells	Normal ovaries	NA
Arx	Homeobox gene; Leydig cell development	Inhibition of Leydig cell differentiation	NA	Dysgenic testes
Dhh	Desert hedgehog; signaling through Patched receptor; Leydig cell development	Dysgenic testis or hypospermatogenesis; loss of Leydig cells	Normal ovaries	Gonadal dysgenesis
Dmrt1/ *Dmrt2*	Transcription factors; contain phylogenetically conserved sex differentiation domains	Overproliferation of immature Sertoli cells; loss of post-meiotic germ cells	Normal ovaries	9p monosomy associated with gonadal dysgenesis, ovotestis, dysgenic or cryptorchid testis
Dax1	Orphan nuclear receptor; dose-dependent anti- and pro-testis functions	Progressive loss of spermatogenesis Gain of function: ovotestes	Normal ovaries	Loss of spermatogenesis Gain of function: XY gonadal dysgenesis
Wnt4	Signaling through Frizzled receptor; required for testis and ovary development	Dysgenic testes Gain of function: disordered vasculature and reduced steroidogenesis	Androgen synthesis with masculinization Gain of function: normal ovaries	Müllerian dysgenesis and virilization in XX Gain of function: cryptorchidism, dysgenic testis or gonadal dysgenesis
Amh	Growth factor; member of transforming growth factor-β family; müllerian duct regression in males	Leydig cell hyperplasia; loss of spermatogenesis Gain of function: inhibition of Leydig cell differentiation	Normal ovaries Gain of function: ovarian degeneration, Sertoli cell and tubule development	Persistent müllerian duct syndrome with testicular dysgenesis and infertility

Known genes regulating gonadal determination and testicular development are based on murine knockout studies and reported human mutations. Transgenic mouse gonadal phenotype describes the effects of homozygous deletion, unless indicated otherwise. Clinical gonadal phenotype refers to loss of function mutations in males, unless otherwise indicated. NA, not available; Wtl, Wilms' tumor 1; *Sf1*, steroidogenic factor 1; *Emx2*, empty spiracles homolog 2; *Pbx1*, pre-B-cell leukemia transcription factor 1; *Lhx1*, LIM homeobox 1; *Lhx9*, LIM homeobox 9; *M33/Cbx2*, M33 polycomb-like protein/chromobox homolog 2; *Tcf21*, transcription factor 21; *Igf1r*, insulin growth factor 1 receptor; *Ir*, insulin receptor; *Irr*, insulin-related receptor; *Sry*, sex-determining region Y chromosome; *Sox8/9*, SRY-box containing genes 8 and 9; *Gata4*, GATA transcription factor 4; *Fog2*, Friend of *Gata2*; *Fgf9*, fibroblast growth factor 9; *Pdgfrα*, platelet-derived growth factor receptor α; *Arx*, aristaless related homeobox gene; *Dhh*, desert hedgehog; *Dmrt*, doublesex and mab-3 related transcription factor; *Dax1*, dosage-sensitive sex reversal/adrenal hypoplasia congenita X chromosome; *Wnt4*, wingless-type MMTV integration site family, member 4; *Amh*, anti-müllerian hormone. See text for references.

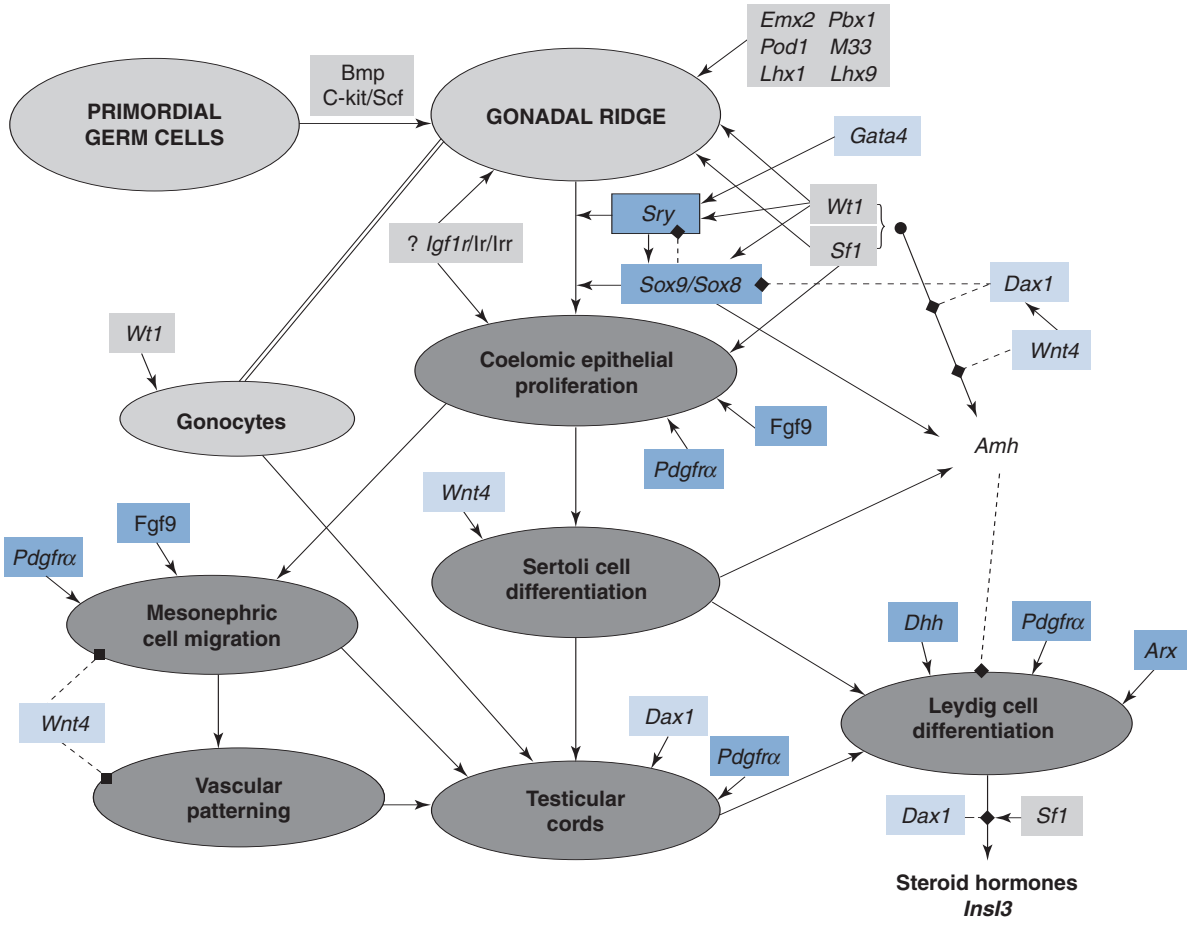

Figure 66.1 Key events and regulatory mechanisms of gonadal and testicular determination based on studies in mice. Solid arrows denote pathways that are directly or indirectly activated by specific events or signals, whereas inhibitory processes are specified by dashed lines. Structure/genes active prior to sex determination (light gray), testis-specific development (dark gray), genes regulating testis development (dark blue), and genes that have roles in both testis and ovarian development (light blue) are noted as such. Bmp, bone morphogenetic proteins; SCF, stem cell factor; *Emx2*, empty spiracles homolog 2; *Pbx1*, pre-B-cell leukemia transcription factor 1; *Pod1*, capsulin/epicardin/*Tcf21*; M33, M33 polycomb-like protein/chromobox homolog 2; *Lhx*, *LIM* homeobox; *Wt1*, Wilms' tumor 1; *Sf1*, steroidogenic factor 1; *Sry*, sex-determining region Y chromosome; *Sox8/9*, *SRY*-box containing gene 8/9; *Gata4*, *GATA* transcription factor 4; *Igf1r*, insulin growth factor 1 receptor; *Ir*, insulin receptor; *Irr*, insulin-related receptor; Fgf9, fibroblast growth factor 9; *Dax1*, dosage-sensitive sex reversal/adrenal hypoplasia congenita X chromosome; *Wnt4*, wingless-type MMTV integration site family, member 4; *Pdgfrα*, platelet-derived growth factor receptor α; *Amh*, anti-müllerian hormone; *Dhh*, desert hedgehog; *Arx*, aristaless related homeobox gene; *Insl3*, insulin-like 3. For further details, see Table 66.1 and text.

CBX2), is associated with severe dysmorphogenesis or absence of gonads (see Table 66.1). Affected fetuses are not viable due to other severe anomalies, including renal agenesis in some cases. The exact function of these proteins in stabilization and development of the gonadal ridge is not known but probably involves a role in cell proliferation.[1] Similarly, defective cell proliferation may be the cause of failed gonadal determination in mice lacking insulin-like receptor signaling following deletion of the insulin growth factor receptor 1 (*Igf1r*), insulin receptor (*Ir*), and insulin-related receptor (*Irr*).[1,16] *Pod1* (capsulin/epicardin/*Tcf21*), a basic helix–loop–helix transcription factor, functions as a repressor of *SF1* in the genital ridge. *Pod1* knockouts of both sexes have gonads that show failed development with aberrant up-regulation of steroidogenic cells and increased apoptosis.[17]

Testis determination

The first definitive step in testis determination is expression of *SRY* by pre-Sertoli cells followed by their subsequent differentiation.[1,2] Sertoli cells then

direct differentiation of other cell types and induce mitotic arrest of germ cells. Testicular organogenesis involves a complex interplay of many genes, some of which influence development of both gonadal types (see Figure 66.1). Careful studies of gonadal architecture, concomitant gene expression, and transgenic phenotypes indicate that precision in the timing and degree of gene expression is crucial. Functional redundancy of critical pathways is also evident.

SRY is expressed in the human XY gonad at 41 days' gestation.[5] Although downstream signaling pathways have not been precisely delineated, it is known that murine *Sry* rapidly induces expression of the related HMG-box gene *Sox9*,[18] which is also expressed concurrently with *SRY* in the human fetal testis.[5] Both genes are essential and sufficient for initiating the testis development pathway in indifferent XY and XX gonads.[19] In both mice and human fetuses, *Sox9* expression is closely linked to that of *Sry*; however, humans appear to be more susceptible than mice to changes in dosage of both genes. Another important SRY-like gene, *Sox8*, has been shown to function cooperatively with *Sox9* in regulation of downstream signaling, and gonad-specific targeted deletion of *Sox8* and *Sox9* produces a more severe phenotype than knockout of *Sox 9* alone.[19,20] Despite its key role in testis development, mutations of *SRY* are found in only 15–20% of individuals with XY gonadal dysgenesis. *SOX9* mutations in humans are associated with the campomelic dysplasia in addition to gonadal dysgenesis[2] and a possible role for *SOX8* in clinical XY gonadal dysgenesis has not been reported. Therefore, other genetic and/or environmental factors must influence the process of testicular determination. Some candidate genes have been identified, as discussed below, but additional uncharacterized autosomal loci may also modulate function of these critical genes and produce the phenotype of XY gonadal dysgenesis.[21]

The earliest indication of testis determination is proliferation of the coelomic epithelium adjacent to the primordial gonad[1] (see Figure 66.1). In the fetal mouse, proliferating cells migrate into the gonad, stimulated by *Fgf9* (fibroblast growth factor 9) and *Pdgfrα* (platelet-derived growth factor) signaling, and differentiate into Sertoli and other gonadal cell lineages. *Pdgfrα* is also required for later formation of testis cords and Leydig cell differentiation. Homozygous deletion of either gene produces partial or complete failure of testis development or, in *Fgf9* knockout mice, development of ovaries.[22,23] Two other genes required during the early phases of testicular determination are the transcription factor *Gata4* (GATA-binding protein 4) and *Wnt4* (wingless-type MMTV integration site family, member 4). *Gata4* directly or indirectly enhances SRY function via interaction with its cofactor, Friend of GATA (*Fog2*) and enhances Sertoli cell proliferation and differentiation; functional knockouts have gonadal dysgenesis or dysgenic testes.[24] *Gata4* also influences ovarian development by a mechanism that remains poorly defined. Similarly, *Wnt4* is required for Sertoli cell differentiation, but has other functions that promote ovarian differentiation (see below).[25] In man, *GATA4* expression in Leydig, Sertoli, and germ cells is already present in the fetal testis at 12 weeks' gestation, the earliest time point studied, and peaks 6 weeks later.[26] Expression is reduced in testes of males with androgen receptor defects, suggesting hormonal control, but is normal in testes of cryptorchid boys.

Differentiation of adequate numbers of Sertoli cells is critical for downstream events in testicular differentiation. *Fgf9* and *Pdgfrα* signaling stimulates mesonephric cells to migrate into the developing gonad, a process that is sexually dimorphic and necessary for formation of the testicular cords and the testis-specific vasculature.[1,22,23] These processes are blocked in ovaries by Wnt4 and in testes of XY fetuses exposed to increased Wnt4 dosage.[27,28] Sertoli cells surround gonocytes already present within the gonad to form testicular cords, with subsequent inhibition of germ cell mitosis. Germ cells located in an ectopic extratubular position either fail to survive or inappropriately enter meiosis. Testicular cord formation also requires *Dax1*, an orphan nuclear receptor that maps to the Xp21 duplication region associated with clinical XY sex reversal and therefore previously considered an ovarian determination or antitestis gene.[29] Transgenic mouse studies confirm that *Dax1* overexpression may lead to ovotestis formation in XY fetuses.[30] However, loss of *Dax1* function in mice is associated with spermatogenic failure in testes, but normal ovaries, data that support a role for this gene in development of the testis but not the ovary.[31] *Dax1* also inhibits expression of *Sf1* and genes involved in hormone production by Leydig and Sertoli cells.[32] In humans, *DAX1* is expressed in the indifferent fetal gonad and transcription persists at low levels in both sexes throughout the period of sexual differentiation.[5] Clinically, *DAX1* mutations are associated with hypogonadotropic hypogonadism, but an intrinsic abnormality in germ cell differentiation is also present, which precludes spermatogenic response to gonadotropin therapy.[33]

DMRT1 and *DMRT2* (*doublesex* and *mab-3* related transcription factors 1 and 2) are genes located within the 9p deletion critical region associated with clinical XY gonadal dysgenesis and sex reversal. They are therefore candidate genes for testis determination downstream of *SRY*.[34] Although specific mutations have not yet been identified in these genes, they contain highly conserved DNA-binding domains that are also present in the sex-determining genes *doublesex* (*Drosophila*) and *mab-3* (*C. elegans*). In mice with homozygous deletion of *Dmrt1* alone, testes form but Sertoli cell maturation and postmeiotic spermatogenesis are abnormal.[35] It is not clear if both genes are needed for testis determination or if there are species-specific differences in DMRT function.

Proper differentiation of the testicular cords and vasculature is also necessary for establishment of the interstitial cell compartment.[1] Desert hedgehog (*Dhh*),[36] a *Drosophila* homolog in the hedgehog signaling pathway, *Pdgfrα*[22] and the homeobox gene *Arx*[37] are required for Leydig cell development. However, human mutations in the *DHH*[38] and *ARX*[37] genes are associated with more generalized failure of testicular development (see Table 66.1). *Dhh* and *Pdgfrα* function via paracrine mechanisms, as they are expressed in Sertoli and interstitial cells, respectively. These data indicate that interaction between the various testicular cell types is essential for normal development and function of the testis.

Anti-müllerian hormone (AMH, or müllerian-inhibiting substance) is a sensitive indicator of the function of Sertoli cells at the time of their differentiation and in postnatal life.[1,39,40] Moreover, secretion of AMH is regulated by many genes important in the testis determination pathway and is inhibited by Wnt4 and Dax1 in the ovary. Like Wnt4 and Dax1, Amh has been shown to have variable effects in murine testis and ovary that are dose-related. Males

Table 66.2 Genetic regulation of testicular descent

Gene	*Function*	*Transgenic mouse phenotype*	*Clinical phenotype*
Insl3	Insulin-like growth factor; stimulates development of the mesenchymal gubernaculum	Perirenal testes	Mutations rare in isolated cryptorchidism
Great/Lgr8	Receptor for insl3, present in gubernacular cells	Perirenal testes	Mutations rare in isolated cryptorchidism
Desrt/ARID5B	AT-rich interaction domain DNA-binding protein	Inguinal testes	NA
HoxA10/HoxA11	Homeobox genes involved in embryo patterning	Perirenal, abdominal, or inguinal testes; epididymal and vasal anomalies	Mutations rare in isolated cryptorchidism
Tgfβ$_2$	Transforming growth factor signaling	Failure of abdominal descent in male fetus	NA
Ar	Androgen receptor signaling	Spontaneous genetic mutation; testes at internal ring	Pelvic, abdominal, inguinal, or labial testes
Aromatase	Conversion of testosterone to estradiol	Overexpression: cryptorchidism	One case of inguinal cryptorchidism
Gata1	Transcription factor	No gonadal phenotype; expressed in Sertoli cells	Familial dyserythropoietic anemia; one report of associated inguinal cryptorchism in brothers

Candidate genes regulating testicular descent are based on transgenic mouse studies and human mutations associated with cryptorchidism. Transgenic mouse phenotype describes the effects of homozygous deletion, unless specified otherwise. Clinical phenotype refers to loss of function mutations. NA, not available; *Insl3*, insulin-like 3; *Great/Lgr8*, G-coupled protein receptor affecting testicular descent/leucine-rich repeat-containing G-protein coupled receptor 8; *Desrt/ARID5B*, developmentally and sexually retarded with transient immune abnormalities/AT-rich interaction domain 5B; *HoxA10/A11*, homeobox A10/A11; *TGFβ*$_2$, transforming growth factor β_2; *Ar*, androgen receptor; *Gata1*, GATA transcription factor 1. See text for references.

with deletion of *Amh* have impaired testicular development, characterized by reduced spermatogenesis and Leydig cell hyperplasia, in addition to persistence of müllerian ducts. Although not well studied, lack of AMH in humans may also adversely affect testicular development, given that males with persistent müllerian duct syndrome are prone to infertility and testicular tumors.[41] Transgenic overexpression of Amh in mice causes inhibition of Leydig cell differentiation in testes and sex reversal in ovaries.[39]

Mechanisms of testicular descent

The human fetal testis is located adjacent to the internal inguinal ring at the end of the first trimester.[42] During the second trimester, a dramatic increase in size of the gubernaculum testis occurs, which allows dilation of the inguinal canal and migration of the processus vaginalis.[43] Finally, starting at 24 weeks' gestation, testes begin a rapid traversal through the inguinal canal. The anatomic and biochemical changes involved in development of the gubernaculum have been studied extensively in rodent and pig fetuses,[44] but the signaling pathways involved remain poorly understood. It is known that gubernacular function depends upon testicular hormones and/or factors that induce its growth, proliferation, and subsequent migration, with the testis, into the scrotum.

Genetic diseases typically associated with gonadal dysgenesis, such as *WT1* mutations,[8] *WNT4* (gain of function) mutations,[28] and 9p monosomy[45] may also present with isolated cryptorchidism. Similarly, mutations of the androgen receptor (AR) may be associated with impaired testicular descent, but phenotypes are variable.[46] Many loci are linked to syndromes associated with cryptorchidism.[47] However, until recently, there were no gene candidates for non-syndromic cryptorchidism. One promising candidate has been identified as INSL3 (insulin-like 3),[48] a hormone in the relaxin family that is probably the non-androgenic testicular factor that is the primary stimulus to gubernacular growth.[49] INSL3 binds to a specific receptor, *Rxfp2* (also known as G-protein coupled receptor affecting testicular descent, or GREAT) that is present in the gubernaculum.[50] Homozygous deletion of *Insl3* or *Rxfp2* in mice is associated with perirenal testes and failure of prenatal development of the gubernaculum. Although *INSL3* and *RXFP2* appear to be ideal candidates for human non-syndromic cryptorchidism, a mutation in one of these genes is present in less than 5% of cases (Table 66.2).[51] It is likely that variants in multiple genes, and possibly environmental exposures,[52] contribute to failure of testis descent.

Some progress in identifying mechanisms of testicular descent has been made by screening fetal mouse gubernacula for expression of cytoplasmic and receptor tyrosine kinases and members of the insulin receptor family.[53] These data indicate that many genes, including *Pdgfrα*, *Igf1r*, *Ir*, and members of the *Eph* and *Egfr* (epidermal growth factor receptor) signaling pathways are expressed in the gubernaculum during development. Characterization of the relative importance and roles of these signals awaits further studies. Additional potential members of signaling pathways involved in testicular descent have been identified from transgenic mouse models and clinical studies. These include the transcription factors *HoxA10*,[54] *HoxA11*[55] (homeobox genes), *Gata1*[56] (GATA binding protein 1), and *Desrt/Arid5B*[58] (developmentally and sexually retarded with transient immune abnormalities/AT-rich interaction domain 5B), and $Tgf\beta_2$[57] (transforming growth factor β_2) (see Table 66.2). Transgenic deletion of *HoxA10* or *HoxA11* is associated with cryptorchidism and anomalies of wolffian duct derivatives, but mutations of the human homologs of these genes are uncommon in boys with cryptorchidism[59,60] (unpublished observations). A *GATA1* mutation was reported in a family with hematologic abnormalities and cryptorchidism, but it is not clear if failure of testicular descent was a consequence of the mutation. *AR* variants that reduce but do not eliminate function, such as increased GGN repeats, may increase the risk for cryptorchidism.[61] Similarly, experimental up-regulation of the aromatase gene[62] is associated with increased estrogen production and cryptorchidism but a reported loss of function mutation in this same gene produced inguinal cryptorchidism in an affected man.[63] As with testis determination, experimental and clinical data do not necessarily correlate, and so far the factors contributing to failure of testicular descent in human fetuses remain unknown in most cases.

Calcitonin gene-related peptide (CGRP) is expressed in the muscular portion of the rat gubernaculum and in the sensory nucleus of the genitofemoral nerve.[64] A role for CGRP in migration of the rat gubernaculum is supported by data showing differential expression of this signaling molecule in rats with cryptorchidism. However, no studies have examined the effect of loss of function of the *CGRP* gene on testicular descent. It remains unclear whether changes in expression of *CGRP* is a cause or effect of failure of descent in rats, or if its role in cremaster

muscle function is applicable to the etiology of human cryptorchidism.[65] Preliminary analysis of the *CGRP* gene has failed to show mutations associated with clinical cryptorchidism.[66]

Early testicular development

Survival and proliferation of primordial germ cells is dependent on bone morphogenetic proteins (BMPs), signaling via the C-kit receptor tyrosine kinase and its ligand, stem cell factor (SCF), and other signaling molecules.[67] In human fetuses, these cells become localized within the testicular cords by the 8th week of gestation.[6] By the second trimester, three distinct subpopulations of germ cells – gonocytes, prespermatogonia, and intermediate spermatogonia – are distinguishable within the tubules based on immunohistochemical characteristics. Along with differentiation, apoptosis (programmed cell death) is an ongoing process throughout gestation in human germ cells as well as in Sertoli and Leydig cells and has an important role in establishing a normal population of cells in the testis.[68]

In mice, migration of undifferentiated germ cells to the tubule periphery and association with Sertoli cells via adhesion molecules occurs in the 1st week of life.[69] The process of migration is not well characterized but requires Sertoli cell signaling, thyroid hormone, and perhaps other hormones and/or testicular factors. Germ cell survival within tubules in neonatal mice is also mediated by C-kit and SCF. Maturation to spermatogonial stem cells is a process that is critical for long-term maintenance of adequate spermatogenesis.[70] Failure of maturation leads to excess apoptosis or persistence of undifferentiated cells that may predispose to future malignant transformation. Direct evidence for regulation of this process in newborn boys by specific factors is lacking. However, failure of germ cell maturation has been identified as a negative prognostic factor in human cryptorchidism.[71]

Maturation of Sertoli and Leydig cells is also essential for spermatogenesis. Active proliferation of Sertoli cells occurs in the perinatal and peripubertal periods and support of sufficient numbers of germ cells depends on subsequent maturation of these cells.[72] Mature Sertoli cells can be identified by expression of Wt1, GATA1, $p27^{Kip1}$ (a cyclin-dependent kinase inhibitor) and AR, whereas persistent expression of AMH, aromatase, NCAM (neural cell adhesion molecule), and cytokeratin-18 is associated with Sertoli cell immaturity. Similarly, the Leydig cell population is composed of distinct fetal and adult types.[73] Adult Leydig cells differentiate from interstitial mesenchymal precursors during the postnatal period through a series of maturational steps. This process is regulated by gonadotropins, androgens, AMH, thyroid hormone, and growth factors. Failed maturation of Sertoli and/or Leydig cells may be the underlying cause of testicular dysfunction, also called 'testicular dysgenesis syndrome', which is observed in cases of cryptorchidism, testicular cancer, and/or hypospermatogenesis.[72]

Conclusions

Normal testicular development and descent requires multiple signaling pathways, many of which have not been elucidated. Failure or reduced expression of only one of these signals may produce a wide spectrum of phenotypic abnormalities that is indistinguishable from other causes. As development is normally associated with phases of proliferation, differentiation, and apoptosis, alterations in any of these programs may ultimately reduce testicular hormone secretion and/or spermatogenesis. Moreover, primary defects in development of one testicular cell type may affect patterning and long-term function of the entire organ. In the future, genetic analysis of boys with abnormalities of testicular development and descent may define more precisely the severity and prognosis of disease among individuals with similar phenotypes, and improve our therapeutic approach to these cases.

Key points

- Establishment of the mammalian gonad is an active process that involves expression of multiple urogenital patterning genes and migration of primordial germ cells.
- Testis determination, triggered by *Sry*, requires coelomic epithelial migration for establishment of Sertoli cells, formation of testicular cords, vascular patterning, establishment of interstitial cells within the gonad, and both differentiation and apoptosis of all cell types.
- Many genes, some of which have dual roles in promoting or inhibiting testis-specific events, regulate testis development.
- The ligand/receptor pair INSL3/Great is critical for testicular descent.
- Postnatal spermatogonial differentiation is critical for establishing spermatogenesis.

Gonads, genital ducts, and genitalia 67

Steven E Lerman, Irene M McAleer, and George W Kaplan

Formation of the gonads begins during the first 3 weeks. Approximately 30–50 germ cells become recognizable among the endodermal cells of the caudal portion of the yolk sac near the allantoic stalk. These begin to migrate by ameboid motion towards the genital ridge.

The hindgut begins to develop during this same time frame. Its development was described in Chapter 49. To briefly recapitulate, the hindgut which is endoderm, sends a blind extension caudally which meets the ectoderm of the body wall at the cloacal membrane. The cloacal membrane initially extends from the tail bud to the body stalk, but as the mesoderm grows the extent of the cloacal membrane becomes smaller.

The gonads continue to develop during the 4th week but remain in an indifferent stage. At this time it is impossible to determine the sex of an embryo by examination. The ventromedial surface of the urogenital ridge begins to thicken and bulge into the coelom as a separate genital ridge, which lies medial and parallel to the mesonephric ridge.

The germ cells, which have been migrating dorsally in the wall of the yolk sac and gut, reach the gonadal ridge by the middle of the 5th week (Figure 67.1). It is during this time that the genital tubercle appears on

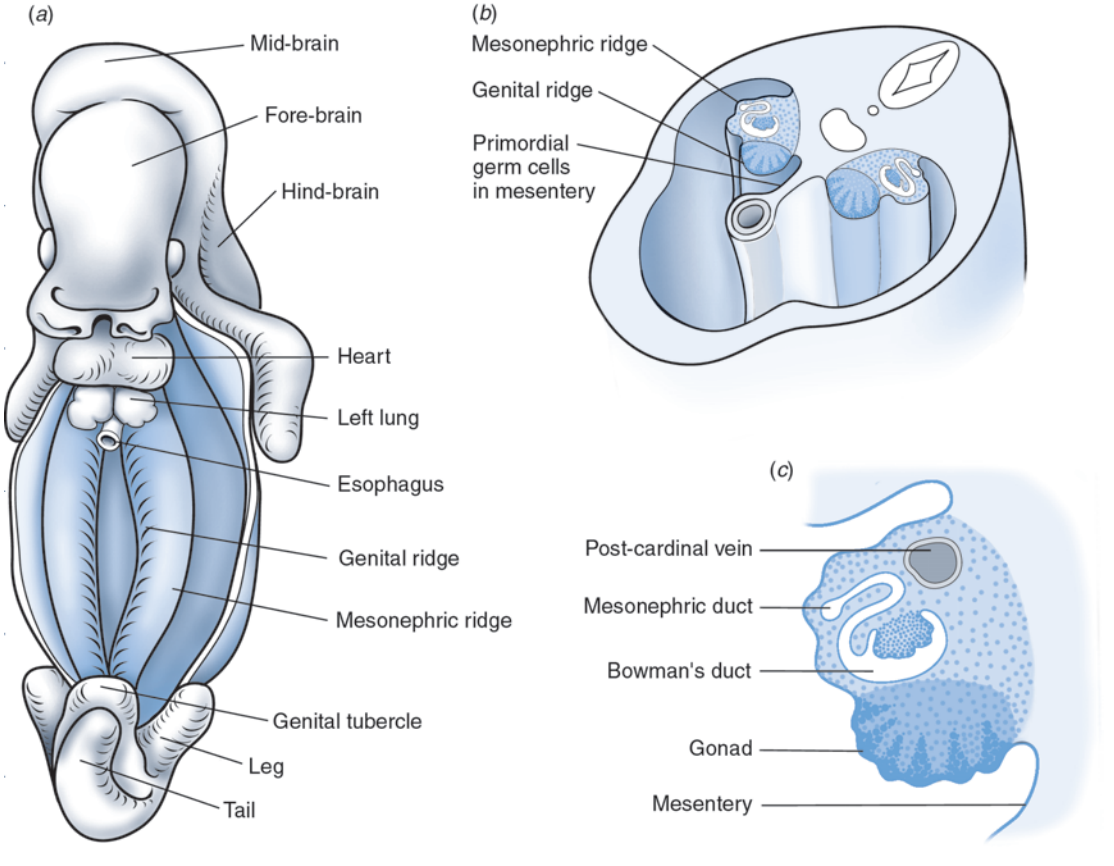

Figure 67.1 Urogenital ridge in the human: (*a*) 9 mm ventral view; (*b*) 7 mm transverse view; and (*c*) 10 mm transverse view. (Reproduced from Arey,[1] with permission.)

the ventral midline between the umbilical cord and the tailbud. The tubercle has a thin urogenital groove caudally, the floor of which is the cloacal membrane and the sides are the urogenital folds. At the same time the cloaca is divided into an anterior urogenital sinus and a posterior rectum by the urorectal septum.

During the 6th week an indifferent gonad is recognizable in both sexes and consists of superficial germinal epithelium and an internal blastema derived from ingrowth of coelomic epithelium. The blastema forms into primary or medullary sex cords, and the germ cells and mesenchyme come to lie between these cords. The urogenital ridge is attached broadly near the root of the mesentery. In both sexes a groove appears in the urogenital ridge, located laterally on the mesonephros near the cephalic end. The cranial end of this groove remains open while caudally it begins to close into a tube (the müllerian duct) (Figure 67.2). There is progressive caudal growth of the solid, blind end of the müllerian duct, guided by the mesonephros. Near the cloaca the urogenital ridges swing mesiad into the genital cord. The cranial end of the müllerian duct is forced laterally by the enlarging suprarenal glands and kidneys. Hence, each müllerian duct has two bends, a cranial one and a caudal one (Figure 67.3).

During the 7th week in the male the attachment of the gonads to the mesonephros becomes the mesorchium. The medullary sex cords fuse with mesonephric tubules to form ductuli efferentes (Figure 67.4). Some mesonephric tubules cephalad to this area persist as vestigial structures associated with the epididymis and spermatic cord (the appendix epididymis, the superior and inferior vasa aberrantia, and

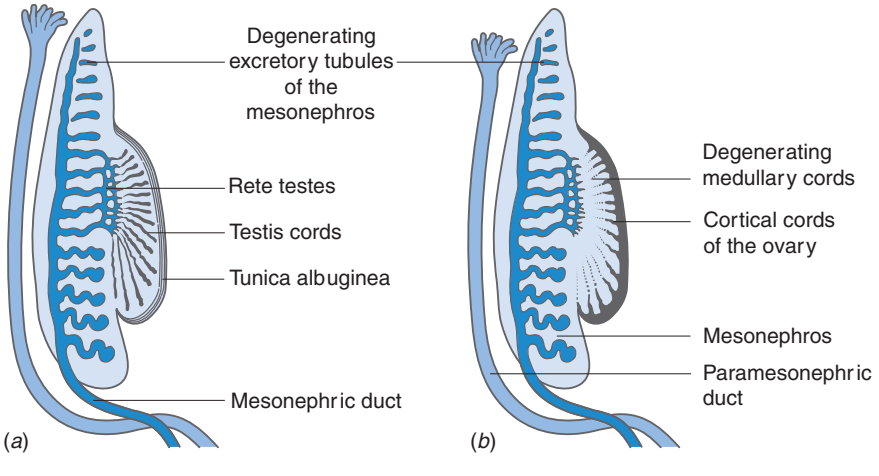

Figure 67.3 Diagram of the genital ducts in the 6th week of development in the male (*a*) and female (*b*). The mesonephric and müllerian ducts are present in both. Note the excretory tubules of the mesonephros and their relationship to the developing gonad in both sexes. (Reproduced from Sadler,[2] with permission.)

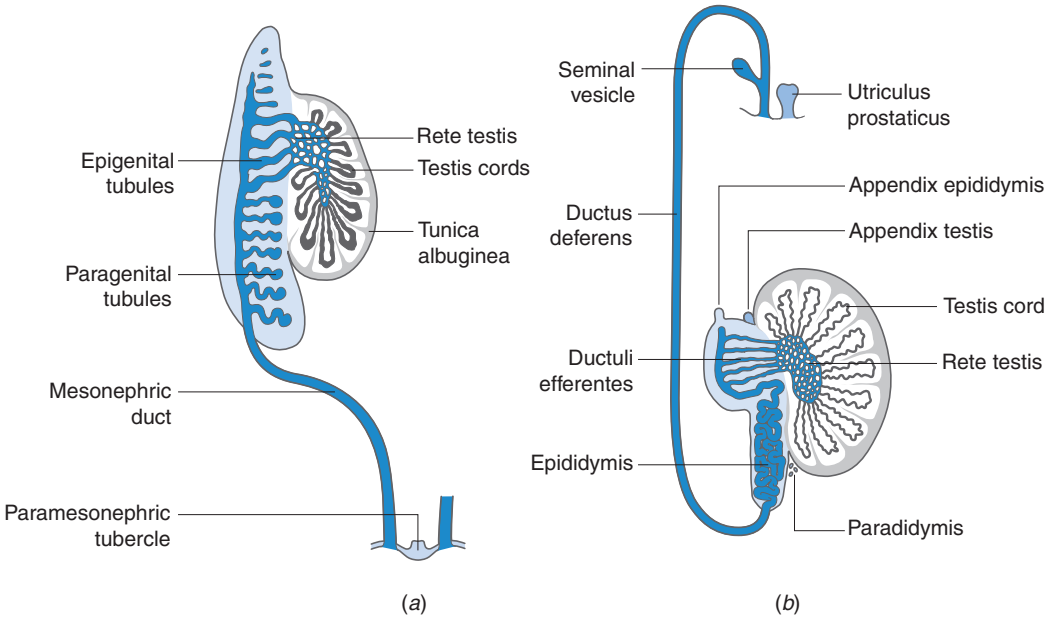

Figure 67.4 (*a*) Diagram of the genital ducts in the male in the 4th month of development. Cranial and caudal (paragenital tubule) segments of the mesonephric system regress. (*b*) Diagram of the genital ducts after descent of the testis. Note the horseshoe-shaped testis cords, rete testis, and efferent ductules entering the ductus deferens. The paradidymis is formed by remnants of the paragenital mesonephric tubules. The müllerian duct has degenerated except for the appendix testis. The prostatic utricle is an outpocketing from the urethra. (Reproduced from Sadler,[2] with permission.)

the paradidymis). The sex cords become separated from the surface epithelium of the gonad by small cells that eventually form the tunica albuginea. The primordial germ cells become incorporated into the testis cords, and these cords become arranged radially, separated by a proliferation of mesenchyme. The cords eventually converge towards the blastemal mass, emerging as the primordia of the rete testis. In the female at this time the round ligament begins to form.

The genital tubercle elongates into a phallus and its tip rounds into the glans (Figure 67.5). Genital swellings appear lateral to the phallic base. The urogenital sinus opens at the base of the phallus by rupture of the cloacal membrane. In the male the corpora cavernosa begin to appear from mesenchymal columns in this area.

The upper five-sixths of the mesonephric ridge has been lost by the 8th week and becomes the diaphragmatic ligament of the mesonephros, which eventually will become the suspensory ligament of the gonad.

In the male, the tunica albuginea has formed a definite encapsulating layer on the gonad, and the gubernaculum begins to form. The phallus elongates, as does the urethral groove and the genital swellings rotate caudad.

In the female, clusters of indifferent cells and primordial germ cells appear. These fall into a dense primary cortex and a looser primary medulla. A mass bulges from the medulla into the mesovarium to form the rete ovarii (Figure 67.6). The suspensory ligament of the ovary is formed from the cephalic end of the genital ridge, while the proper ligament of the ovary is formed from the terminal part of the genital ridge and unites the caudal end of the ovary to the transverse bend of the müllerian duct and eventually to the uterus.

The mesonephros consists of 34 pairs of tubules by the 9th week, but half of them are non-functional. This is the end of the stage of maximal mesonephric development. The cranial eight to 15 pairs project against the rete testis or rete ovarii. The caudal ends of the müllerian ducts have now fused medially and end blindly at Müller's tubercle. The mesonephric ducts are now lateral to the müllerian duct caudally.

Cowper's gland in the male and Bartholin's gland in the female, which are homologues, arise as a pair of solid buds from the endodermal epithelium of the urogenital sinus distal to Müller's tubercle. In the male, they extend backwards, paralleling the urogenital sinus, and penetrate the mesenchyme of the corpus cavernosum urethrae and become glandular. They open into the bulbus urethra. In the female, they open into the vestibule near the hymen.

By the 10th week all of the mesonephric tubules have become discontinuous. The gonads in both sexes lie at the boundary of the pelvis and the abdomen. In

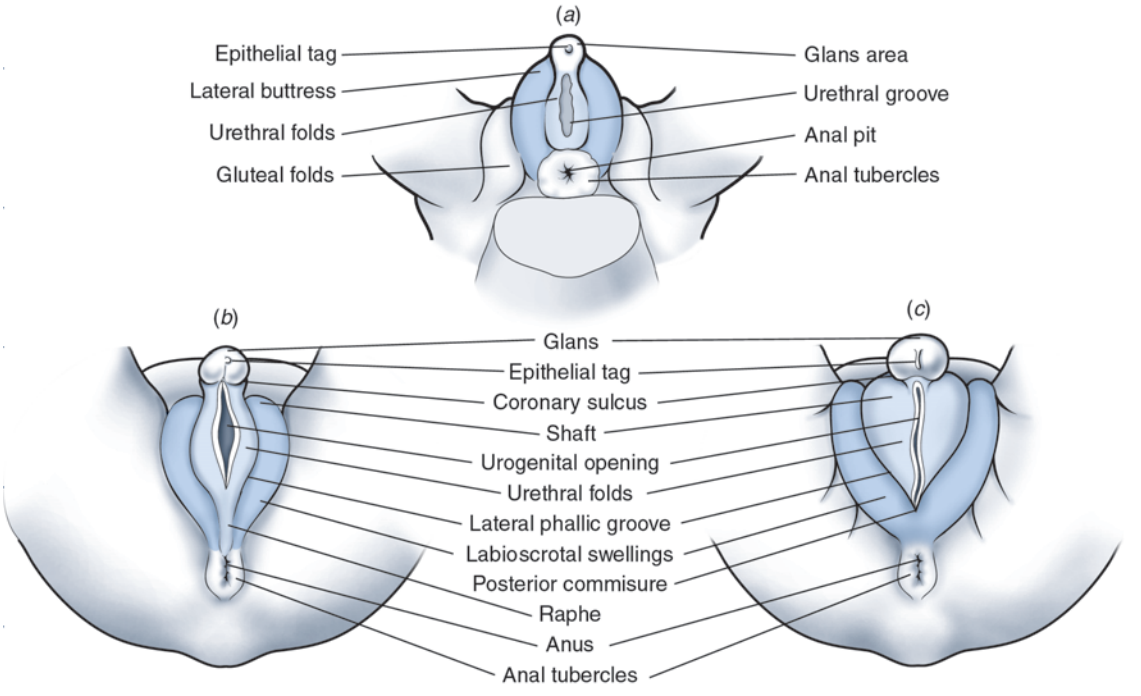

Figure 67.5 Developing external genitalia of the human: (*a*) 7th week; (*b*) male, 10th week; and (*c*) female, 11th week. (Reproduced from Gray and Skandalakis,[3] with permission.)

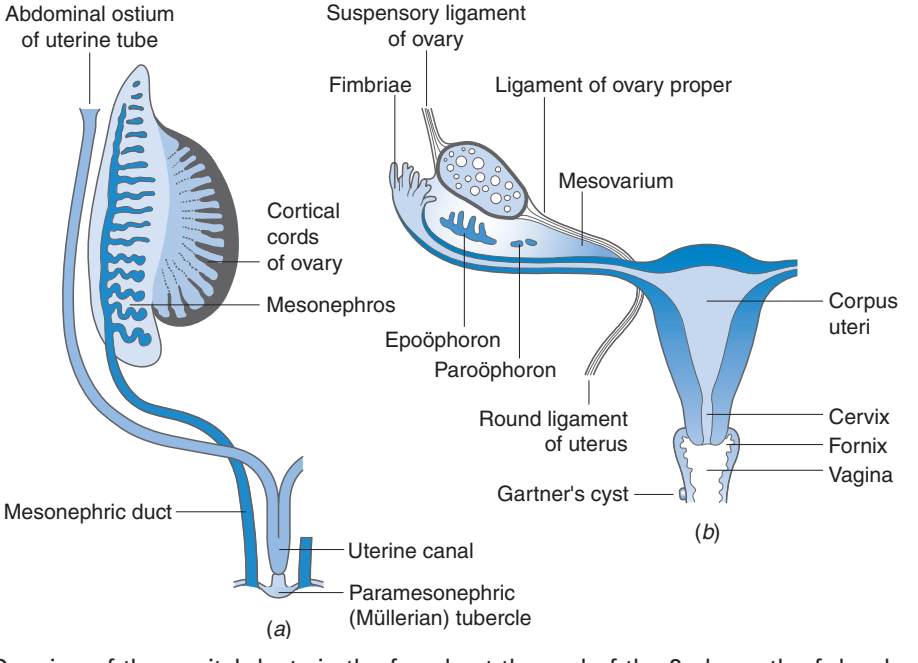

Figure 67.6 (*a*) Drawing of the genital ducts in the female at the end of the 2nd month of development. Note the müllerian tubercle and formation of the uterine canal. (*b*) Drawing of the genital ducts after descent of the ovary. The only parts remaining from the mesonephric system are the epoöphoron, paroöphoron, and Gartner's duct. Note the suspensory ligament of the ovary, ligament of the ovary proper, and round ligament of the uterus. (Reproduced from Sadler,[2] with permission.)

the male, the external genitalia are becoming visible as male structures as a result of secretion of testosterone by the fetal testis. The phallus has become the penis. The edges of the urethral folds begin to fuse progressively from posterior to anterior, forming the urethra and the median raphe. The genital swellings become scrotal swellings, which fuse to form a scrotal septum and raphe.

Table 67.1 Embryologic remnants

Male	Müllerian remnants	Appendix testis Prostatic utricle
Female	Wolffian remnants	Epoöphoron Paraoöphoron Gartner's duct

In the 11th week the prostate arises as multiple outgrowths of endoderm both above and below the mesonephric ducts. These outgrowths arise in five different groups, each of which corresponds to a future prostatic lobe. The buds grow into the surrounding mesenchyme, which in turn provides both connective tissue and smooth muscle. In the female, the homologues of the prostate are the urethral glands, which are drained by Skene's ducts on each side.

Littre's glands bud from the male urethra in the 12th week. In the female, homologues of Littre's glands bud into the vestibule. In the male the processus vaginalis appears as an outpouching at the internal inguinal ring, and the testis lies nearby. The gubernaculum has already formed. The müllerian ducts degenerate owing to the secretion, by Sertoli cells, of müllerian inhibiting factor (MIF). Müllerian remants in the male are the appendix testis from the cranial end and the prostatic utricle from the caudal end of the müllerian duct (Table 67.1).

In the female, the secondary ovarian cortex begins to form in the 12th week by division of cells of the ovarian blastema and by new growth of germinal epithelium. The early ova regress and form the medulla. The ovaries at this time lie at the pelvic brim. The round ligament is complete. Vaginal and uterine musculature appears from the mesenchyme surrounding the müllerian ducts. The distal portions of the müllerian ducts have fused below the caudal bend (Figure 67.7).

In the 13th week, in the male, the seminal vesicles develop as lateral branches off the mesonephric duct. Branching of these seminal vesicles is evident by the 4th month of fetal life, and eventually a muscular coat is gained from the mesenchyme. In the female, the mesonephric ducts begin to regress. Elongation of the fetal pelvis causes a solid epithelial cord to form between the end of the müllerian ducts and the urogenital sinus; this cord will become the upper vagina.

During the 14th week, the penile shaft continues to elongate in the male, and the urethra has fused to the base of glans penis. The penile shaft has a ventral deflection.[4] The prepuce now begins to form as a fold of skin that grows distally. By 5 months of gestational age, preputial formation is complete. The prepuce then fuses to the glans and reseparates from it under the influence of testosterone by the formation of small clefts in the preputial sac. This procedure of separation is incomplete at birth and continues for several years thereafter.

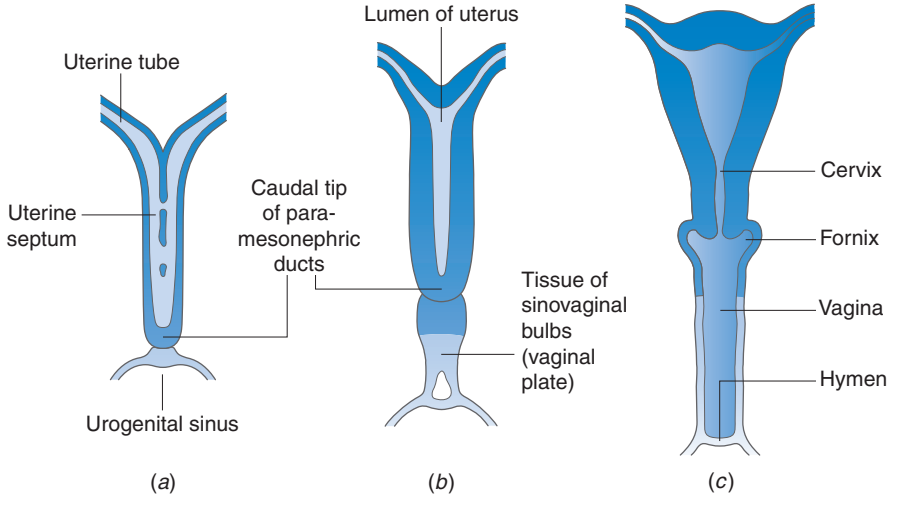

Figure 67.7 Schematic drawing showing formation of the uterus and vagina: (*a*) at 9 weeks, note the disappearance of the uterine septum; (*b*) at the end of the 3rd month, note the tissue of the sinovaginal bulbs; and (*c*) in the newborn, the fornices and the upper portion of the vagina are formed by vacuolization of the müllerian tissue and the lower portion of the vagina is formed by vacuolization of the sinovaginal bulbs. (Reproduced from Sadler,[2] with permission.)

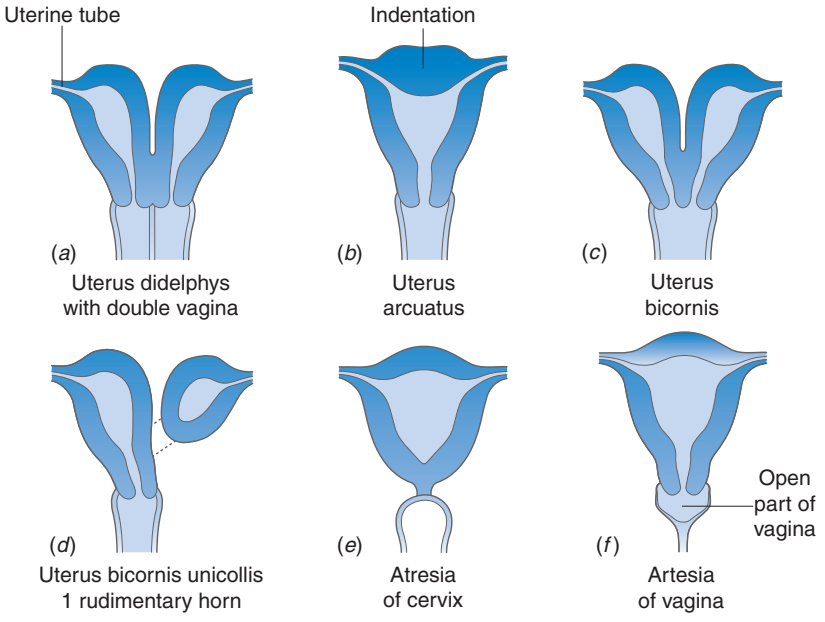

Figure 67.8 Schematic representation of the main abnormalities of the uterus and vagina, caused by persistence of the uterine septum or obliteration of the lumen of the uterine canal. (Reproduced from Sadler,[2] with permission.)

By the 16th week, maximal degeneration of the mesonephric tubules has been attained. The muscles of the perineal floor are visible. The epithelium of Cowper's and Bartholin's glands is glandular in nature. In the testis, interstitial cells are very abundant. In the female, the vagina begins to form a lumen as the fornices appear as clefts in the solid epithelial cord distal to the fused müllerian ducts. The uterus forms as a fusion of müllerian ducts as they move ventrally and medially. Inappropriate fusion can result in uterine structural abnormalites such as bicornuate uterus (Figure 67.8). During this fusion, the broad ligaments are formed. The cervix and the fallopian tubes are now evident.

The vaginal lumen and the prepuce are completely formed by the 20th week. The penile shaft is now straight.[4] Homologous structures between male and female and their embryologic origin are listed in Table 67.2.

The tunica albuginea of the ovary forms during the 24th week. In the male, the lumen of the rete tubules and cranial mesonephric tubules become continuous and form the efferent ductules of the epididymis. The cranial end of the mesonephric duct convolutes, forming the body of the epididymis. The caudal end remains straight, forming the ductus deferens. The terminal end of the mesonephric duct forms the ejaculatory duct. The ampulla of the vas deferens forms from dilation of the ejaculatory duct. The processus vaginalis in the male now begins to move through the inguinal canal.

Formation of the seminal vesicles in the male is complete by the 28th week. The processus vaginalis has herniated through the abdominal wall, formed the inguinal canal, and reached the scrotum. The testis then begins to descend towards the scrotum. Several factors are hypothesized to influence testicular descent. These include gubernacular guidance, increased intra-abdominal pressure,[5] and, possibly, the release of a substance, descendin, from the normal testis.[6] In addition, the genitofemoral nerve has been studied as a potential factor in inducing testicular

Table 67.2 Embryologic homologues

Embryologic structure	Male	Female
Urogenital sinus	Prostatic urethra, prostate	Urethra, upper vagina
Genital tubercle	Glans penis	Clitoris
Genital folds	Urethra, penile shaft	Labia minora
Genital swellings	Scrotum	Labia majora

descent.[7] With normal factors intact, the testicle will reach the ipsilateral scrotum during the third trimester. Testis descent occurs in 60% of males by 30 weeks and 93% of males by 32 weeks.[8] Cryptorchidism is a frequent anomaly whose etiology has been extensively studied but is still incompletely understood. Some instances appear to be due to intrauterine endocrine failures, whereas others seem mechanical. Intra-abdominal testes might result if the processus vaginalis did not form. Ectopic testes might result if the path of descent were obstructed or if the gubernaculum went astray, failing to define a path for the testis to follow into the ipsilateral scrotum. The descent of the ovary is quite comparable to that of the testicle, but the gubernaculum fuses with the lateral margin of the uterus which, therefore, arrests descent of the ovary in the pelvis. Failure of fusion of the gubernaculum to the uterus may allow the ovary to descend into the labia majora.

Major anomalies of these genital organs are frequent, including intersex, hypospadias, and cryptorchidism. If the testis determining factor is present, a testis will develop. In the presence of the testis, MIF will be released by Sertoli cells and lead to regression of the müllerian ducts. In addition, elaboration of testosterone from Leydig cells will cause development of the mesonephric ducts and masculinization of the internal ducts. Masculinization of the external genitalia is dependent on the conversion of testosterone to 5-dihydrotestosterone. Failure of this conversion helps to explain some cases of ambiguous genitalia. In the absence of a testis, an ovary (or streak gonad) forms, the müllerian structures persist, and the external genitalia are feminine.

Hypospadias represents arrested formation of the phallus and phallic urethra. In many instances, the distal hypospadiac urethra is dysplastic, as is the surrounding corpus spongiosum.[9] With severe forms of hypospadias a small müllerian remnant may persist as a diverticulum off the prostatic utricle.

Intersex

68

Hsi-Yang Wu and Howard M Snyder III

Introduction

A rational approach to the patient with intersex relies on understanding the development of the internal and external genital ducts, the steroid synthesis pathway, what is surgically possible, and when surgery should be performed. This chapter focuses on the anatomy, pathophysiology, and classification of intersex states, whereas the surgical approach will be discussed in Chapter 70.

Internal and external genital development

The two key points to remember in understanding the variety of intersex states are that the internal genital development depends on the ipsilateral gonad, and external genital development depends on the presence of testosterone and dihydrotestosterone (DHT). The reduction of testosterone to DHT is catalyzed by 5α-reductase, an enzyme which is

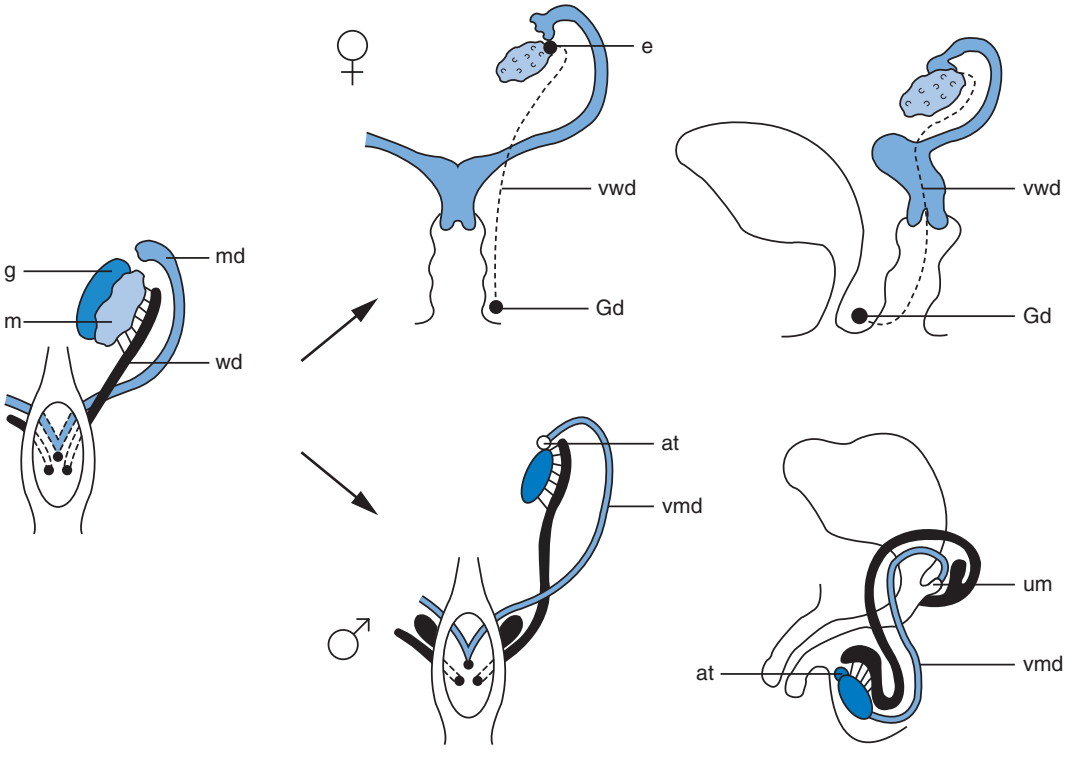

Figure 68.1 Fate of the wolffian and müllerian ducts. In the male, the wolffian duct forms the epididymis, vas, and seminal vesicle. Note the remnants of the müllerian duct. In the female, the müllerian ducts form the fallopian tubes, uterus, and upper third of the vagina. Note the remnants of the wolffian duct. Abbreviations: g = gonad; m = mesonephros; md = müllerian duct; wd = wolffian duct; at = appendix testis; vmd = vestigial müllerian duct; um = utriculus masculinus; e = epoöphoron; vwd = vestigial wolffian duct; Gd = Gartner's duct.

located in genital tissue. If an ovary or streak gonad is present, the internal genital duct will develop along female lines: a uterus and fallopian tube will form. If a testis is present, the internal genital duct will develop along male lines: an epididymis, vas, and seminal vesicle will form. The genital tubercle develops into a phallus if DHT is present, and develops into a clitoris if it is absent or low. Therefore, patients with congenital adrenal hyperplasia (CAH) can have what appears to be a normal male penis despite the presence of two ovaries (Figure 68.1).

Internal genital development

Besides the ovary and testis, patients with intersex can also have two other types of gonads: the streak gonad and the ovotestis. A streak gonad consists of ovarian stroma without ovarian follicles. An ovotestis consists of a mixture of ovarian and testicular tissue. They can be arranged next to each other, in a bilobed 'boxcar' type of arrangement (80%), or one type of tissue can be centrally located, surrounded by a shell of the other tissue (20%).[1] Since it is not always possible to determine which arrangement is present by gross inspection, biopsy of an ovotestis should be performed by opening the gonad widely and taking a deep biopsy.

The gonads exert different effects on the müllerian and wolffian ducts, which are both present at 7 weeks' gestation. Jost's experiments with fetal rabbits showed that when gonads were removed during development, the internal genital structures were always female.[2] The idea that the female structures are the 'default pathway,' and do not require the presence of an ovary came from these experiments. The wolffian duct was felt to require the 'stabilizing' presence of testosterone to prevent involution. When Jost replaced the ovary with testosterone crystals, the wolffian duct remained, along with the müllerian duct.[3] This suggested that a separate protein, later identified as müllerian inhibiting substance (MIS), was secreted by the fetal testis to cause involution of the müllerian duct. In the case of an ovotestis, the fallopian tube is usually present, and the wolffian duct may be present, suggesting that DHT and MIS interact with each other, and that low levels of either hormone result in incomplete action on their target organs (Figure 68.2).

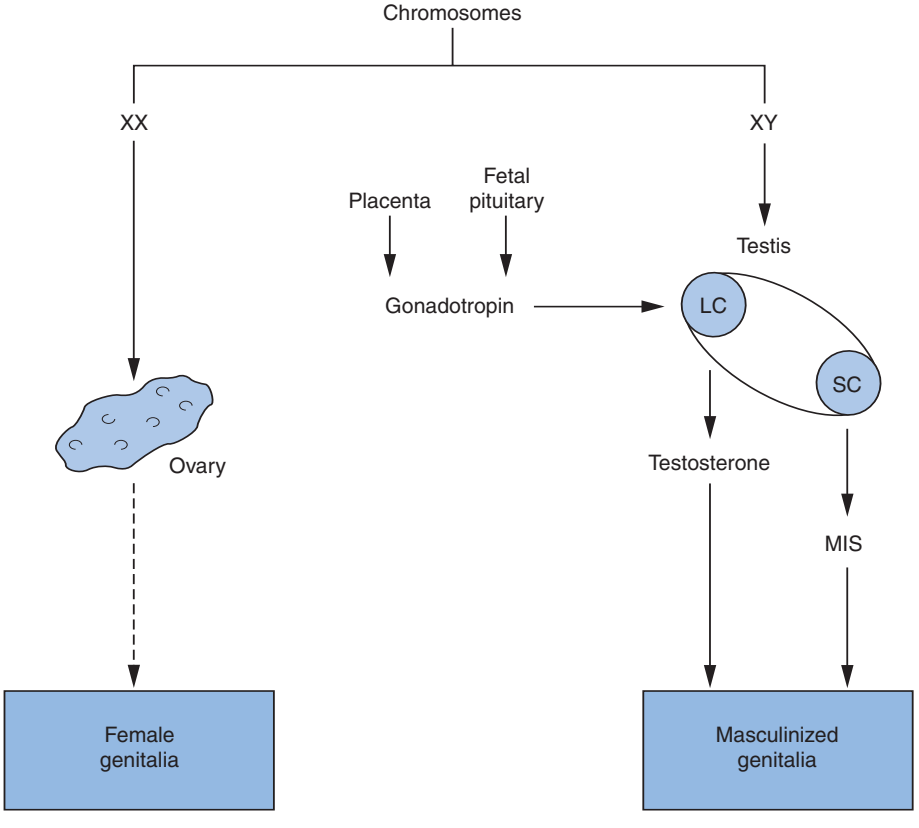

Figure 68.2 Pathways of normal sexual differentiation. The role of the chromosomes is solely to determine the nature of the gonads. Gonadotropin stimulation of the testes releases testosterone. This, together with müllerian inhibiting substance (MIS), determines the nature of the internal ducts and external genitalia. SC = Sertoli cells; LC = Leydig cells.

External genital development

Under the influence of DHT, the urethral plate tubularizes to form the penile urethra with associated spongiosum between 9 and 12 weeks of gestation. The genital tubercle elongates to form the phallus, and the labioscrotal folds fuse in the midline to form the scrotum. Abnormalities in testosterone or DHT synthesis (5α-reductase deficiency) may result in hypospadias, due to failure of the urethra to tubularize to the end of the glans. Without DHT, the genital tubercle develops into the clitoris, the urethra opens onto the perineum, and the labioscrotal folds form the labia majora and minora.

Evaluation of the newborn with ambiguous genitalia

Determining the cause of ambiguous genitalia in a newborn remains an urgent task due to the possibility of salt-wasting CAH, which can be lethal if not recognized and treated appropriately. The history should focus on whether the mother took any hormones during pregnancy, whether there are any family members with intersex disorders, and if there is a family history of infants dying during the first few weeks of life (unrecognized salt-wasting CAH). The differential diagnosis of a phenotypic female with a single perineal opening includes cloacal abnormalities. Hyperpigmented skin suggests high adrenocorticotropic hormone (ACTH) levels. The key point to remember about the examination is that a palpable gonad is usually a testis. Although ovaries can sometimes be found in the inguinal canal in association with large inguinal hernias, they generally do not descend on their own. Ovotestes are sometimes found in the labioscrotal folds. Since the degree of clitoral hypertrophy is not helpful in the diagnosis, the main finding on physical examination is the presence of one or both gonads. An algorithm is outlined in Figure 68.3. The length of the phallus does play a role in making the decision about the feasibility of raising the baby as a male with a functional phallus.

If neither gonad is palpable, then a pelvic ultrasound is obtained to determine whether a uterus is present. A digital rectal examination may also reveal the presence of a cervix. Ultrasound is fairly unreliable for locating gonads. Magnetic resonance imaging (MRI) of the pelvis is helpful if there is a question of the internal anatomy on the ultrasound. A genitogram is helpful to determine the length of the common urogenital sinus in CAH, and should be obtained before performing a feminizing genitoplasty. One method of obtaining

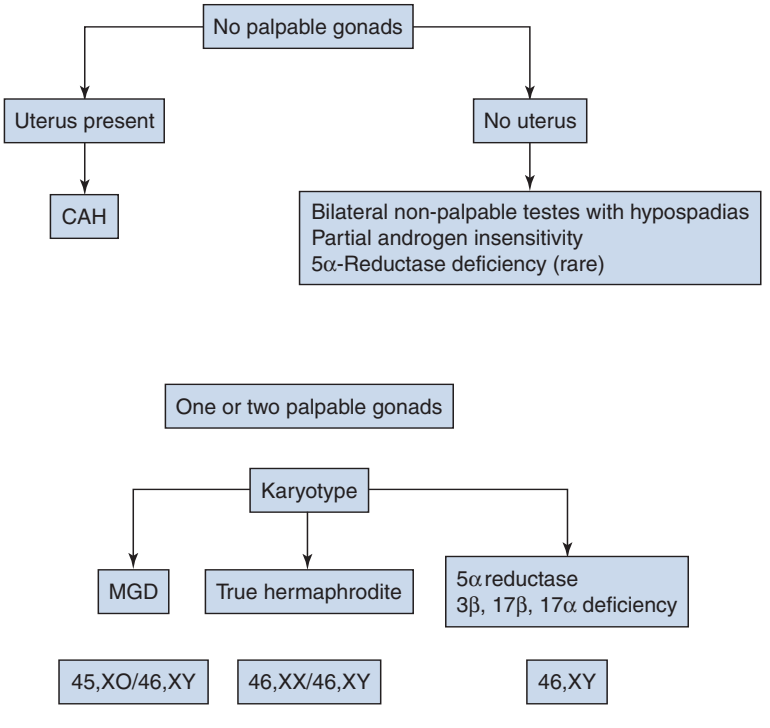

Figure 68.3 Algorithm for newborn ambiguous genitalia. MGD = mixed gonadal dysgenesis; 3β = 3β-hydroxysteroid dehydrogenase; 17β = 17β-hydroxylase dehydrogenase; 17α = 17α-hydroxylase/17,20-lyase.

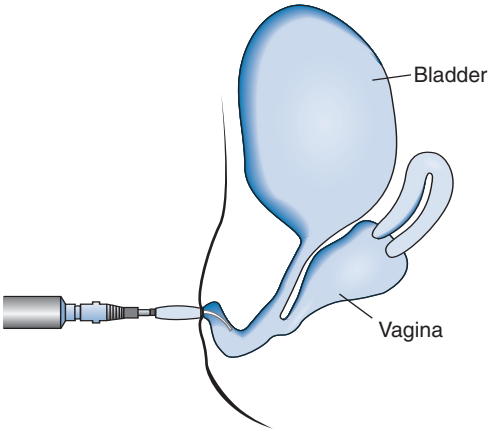

Figure 68.4 Retrograde genitogram for intersex evaluation. (Reproduced from Snyder,[4] with permission.)

good-quality genitograms is to use the tapered end of a feeding tube to occlude the perineal opening. By cutting off the remainder of the feeding tube, a low confluence vagina will still be identified. When the child tightens the external sphincter during contrast instillation, the vagina is preferentially filled[4] (Figure 68.4).

If no uterus is present, then the diagnosis is bilateral non-palpable testes (or bilateral vanishing testes) with hypospadias, partial androgen insensitivity syndrome, or 5α-reductase deficiency. If the hypospadias is proximal, a karyotype can be obtained. If a uterus is present, then the karyotype will confirm that the genotype is 46,XX. Buccal smears, previously used for rapid detection of a Barr body suggesting a 46,XX genotype, are not routinely used since karyotyping is routinely available. Additional serum tests such as 17-hydroxyprogesterone, 17-hydroxypregnenolone, and 11-deoxycortisol will help determine which enzyme defect is the cause of the CAH.

If one or both gonads are palpable and phallic structure is ambiguous, then the diagnosis will depend on the karyotype. The differential diagnosis is mixed gonadal dysgenesis, true hermaphrodite, 5α-reductase deficiency, or a defect in the steroid synthesis pathway. Serum levels of luteinizing hormone (LH), follicle-stimulating hormone (FSH), and testosterone are helpful to determine testicular function and how the hypothalamic–pituitary axis is working. Aside from patients with CAH (elevated 17-hydroxyprogesterone), Turner's syndrome (physical findings and karyotype), or 5α-reductase deficiency (elevated testosterone/DHT), most patients with ambiguous genitalia require gonadal biopsy. Gonadal biopsy can be performed via a Pfannenstiel incision, bilateral inguinal incisions, or laparoscopically. Again, a deep biopsy is recommended to avoid missing the deeper component of the gonad. Frozen section can be used if the diagnosis is fairly clear (such as mixed gonadal dysgenesis with streak gonad) and the parents are aware that tissue discordant with the sex of rearing will be removed. If the diagnosis is unclear, it is better to wait for the permanent section and remove the gonad after the additional information from the biopsy can be included in the decision regarding sex of rearing.

The non-ambiguous types of intersex will not necessarily be detected immediately after birth. Complete or partial androgen insensitivity (CAIS and PAIS) can present as an inguinal hernia in a girl or as amenorrhea. Persistent müllerian duct syndrome presents as an inguinal hernia or an undescended testis in a boy.

Categories of intersex

Allen's classification by gonadal histology is probably the best conceptual framework by which to organize the varieties of intersex conditions:[5]

I. Female pseudohermaphrodite (ovary–ovary)
II. True hermaphrodite (ovary–testis)
III. Male pseudohermaphrodite (testis–testis)
IV. Mixed gonadal dysgenesis (testis–streak)
V. Pure gonadal dysgenesis (streak–streak).

This classification is shown in Figure 68.5. Fertility potential and cancer risk are summarized in Table 68.1.

Female pseudohermaphrodite

Congenital adrenal hyperplasia

CAH is the most common intersex disorder, with 21-hydroxylase deficiency accounting for 95% of all cases of CAH, and 11-hydroxylase deficiency accounting for 5%:[6] both are autosomal recessive disorders. The steroid synthesis pathway is outlined in Figure 68.6. Girls with CAH are noticed at birth from their ambiguous genitalia. The rise in testosterone occurs after the wolffian duct has already regressed, and no MIS is present; thus, the internal anatomy is female. The degree of clitoral hypertrophy varies from minimal to severe, sometimes mimicking a normal penis (Figures 68.7–68.11). Boys with CAH are detected either by newborn screening or by precocious puberty with early development of the penis, scrotum, and skeletal muscle.

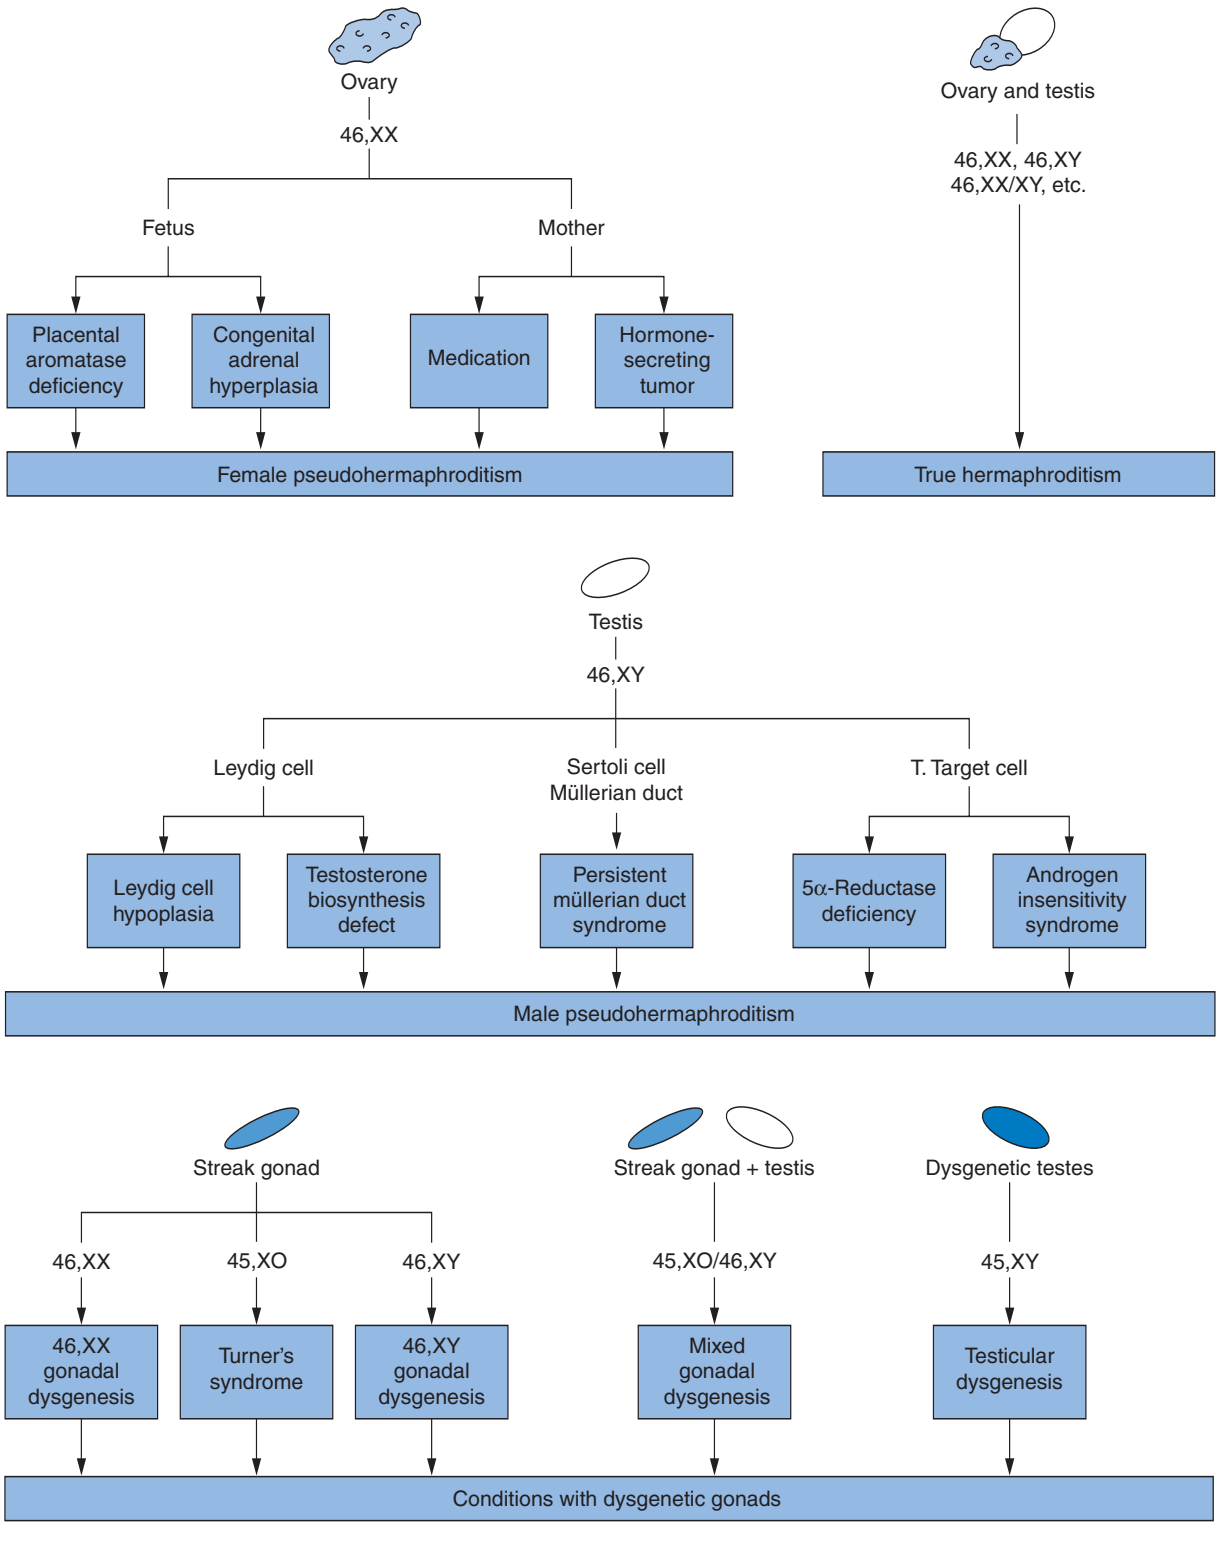

Figure 68.5 Classification of intersex disorders: a scheme based on the histology of the gonads.

21-Hydroxylase deficiency prevents the synthesis of aldosterone and cortisol, and causes ACTH to rise due to a lack of negative feedback. 17-Hydroxyprogesterone is overproduced, which is converted to testosterone, causing the virilization of the external genitals. In a newborn with CAH, the serum 17-hydroxyprogesterone levels are ≥5000 ng/dl, compared with 900 ng/dl in normal newborns.[7] If the defect is 11β-hydroxylase deficiency, 11-deoxycortisol will be elevated as well as 17-hydroxyprogesterone.

Table 68.1 Comparison of genotype, phenotype, fertility, and cancer risk

	Genotype	Genital phenotype	Fertility	Cancer risk
21-Hydroxylase	46,XX	Ambiguous	Yes	No
11β-Hydroxylase	46,XX	Ambiguous	Yes	No
3β-Hydroxysteroid dehydrogenase	46,XY 46,XX	Ambiguous, possible undescended testes	Rare male	No
True hermaphrodite	46,XX (80%) 46,XX/XY (10%) 46,XY (10%)	Ambiguous	Rare females	Rare, if Y chromosome present
Complete androgen insensitivity	46,XY	Female	No	Yes
Partial androgen insensitivity	46,XY	Ambiguous	No	Yes
5α-Reductase deficiency	46,XY	Perineal hypospadias	Rare	No
Persistent müllerian duct syndrome	46,XY	Male	Rare	Testis tumors, no uterine tumors
Congenital lipoid adrenal hyperplasia	46,XY rare 46,XX	Female	No	Yes
17β-Hydroxylase dehydrogenase	46,XY	Female, possible undescended testes (no phenotype in 46,XX)	No	No
17α-Hydroxylase/17,20-lyase	46,XY	Hypospadias, possible undescended testes	No	No
Mixed gonadal dysgenesis	45,XO/46,XY	Hypospadias, undescended gonad	No	Gonado-blastoma
Turner's syndrome	45,XO	Female	No	No
Pure gonadal dysgenesis	46,XX 46,XY	Female	No	Yes, if 46,XY

Patients with 11β-hydroxylase deficiency are often hypertensive because deoxycorticosterone (DOC) is a strong mineralocorticoid (see Figure 68.6). Since there are varying degrees of enzyme deficiency, salt wasting and virilization can be present or absent. The salt-wasting forms usually do not show hyponatremia and hyperkalemia until the first week of life. Plasma renin activity is measured for patients with salt-wasting CAH, and is usually elevated. Patients with 11β-hydroxylase deficiency have low plasma renin due to excess mineralocorticoid.

Three different forms of CAH are commonly recognized: the classic (75%), the simple virilizing (25%), and the non-classic types (unclear). The classic form presents with salt wasting and virilization, the simple virilizing type without salt wasting, and the non-classic type with a normal genital appearance at birth, followed by virilization after puberty.[6] Patients who are not recognized at birth will present with hypotension, nausea, and vomiting. If a mild simple virilizing form is not detected in early childhood, the patient may have progressive clitoral hypertrophy and premature closure of the epiphyses.

Since patients with CAH are fertile, and the majority have a female gender identity and gender role, the controversy over genital surgery for these patients revolves mainly around the timing of surgery, whether neonatal results are as good as those achieved at adolescence, and whether this is balanced by allowing the patient to choose to undergo the procedure.[8] In the severely virilized female patient with CAH, a male sex of rearing may be appropriate since the brain may also be virilized. The indications, timing, and techniques of feminizing genitoplasty are discussed in Chapter 70.

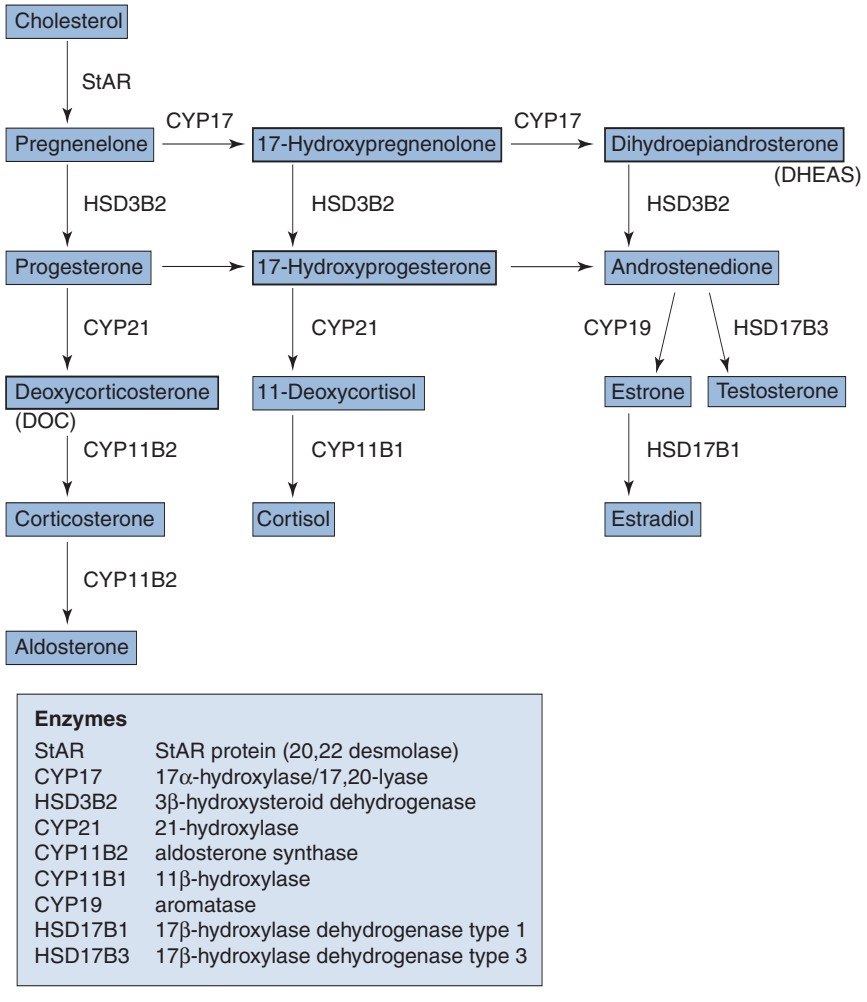

Figure 68.6 Steroid synthesis pathway. (Reproduced from Witchell and Lee,[7] with permission.)

Prenatal treatment

CAH is an autosomal recessive disease; therefore, siblings in an affected family have a 25% risk of being affected. However, since masculinization of the external genitals is only a problem in girls, only one-eighth of subsequent siblings would benefit from prenatal treatment. Prenatal treatment consists of dexamethasone 20 μg/kg twice a day to the mother; 10% of patients develop hypertension, edema, and fluid retention due to treatment during the first trimester. Treatment must start early in pregnancy (7–10 weeks), when the external genitals are forming, and before the diagnosis can be confirmed. To make the diagnosis, chorionic villus sampling (9–10 weeks) is performed. The option of prenatal treatment should be discussed with families who have a child with CAH and are planning to have more children.[6]

Postnatal medical management

Early consultation with a pediatric endocrinologist is helpful in determining which battery of tests to order. Serum 17-hydroxyprogesterone is rapidly available and makes the diagnosis of CAH. Patients are started on glucocorticoid supplementation such as hydrocortisone (Cortef, 10–20 mg/m^2/day). Supplementation of a mineralocorticoid such as fludrocortisone (Florinef, 0.1 mg daily) is recommended if the plasma renin is high.[7] Clitoral hypertrophy can become less prominent with somatic growth if good medical management is maintained. Long-term follow-up with an endocrinologist is necessary, since lifelong treatment and adjustment of medication dosage will be required. 17-Hydroxyprogesterone levels are used to monitor therapy. Examination of the reconstructed vaginal introitus in teenage girls is usually carried out

Figure 68.11 Congenital adrenal hyperplasia, severe virilization. (From Snyder,[4] with permission.)

under anesthesia. One complication unique to boys with CAH is the possibility of developing Leydig cell nodules. These present with bilateral testicular enlargement, and respond to adequate ACTH suppression. If they do not respond promptly, the testes should be biopsied to differentiate this condition from Leydig cell tumor, which usually presents with unilateral testicular enlargement.

Figure 68.12 True hermaphroditism: note the scrotal asymmetry. The left gonad was an intra-abdominal ovotestis.

Figure 68.13 True hermaphroditism: a fully descended ovotestis showing a clear demarcation between the ovarian (left) and testicular (right) portions.

3β-hydroxysteroid dehydrogenase deficiency

Dehydroepiandrosterone (DHEA) causes virilization of 46,XX fetuses, whereas the lack of testosterone leads to undervirilization of 46,XY fetuses. The wolffian structures are maintained. Since the defect is so high in the pathway, pregnenelone, 17-hydroxypregnenolone, and DHEA are all elevated. The child's adrenals are unable to synthesize mineralocorticoids or glucocorticoids, and replacement is required soon after birth.[9]

True hermaphrodite

Patients most often have ovotestes (40% ovotestis/ovary, 15% ovotestis/testis, 34% bilateral ovotestis), but it is possible for an ovary to be present on one side, and a testis on the other (11%). The karyotype is usually 46,XX (74%), but 46,XX/XY (19%) and 46,XY (6%) are also seen.[10] The genital appearance is extremely variable. Most have perineal hypospadias with one palpable gonad, usually on the right (Figures 68.12 and 68.13). The internal genital structures ipsilateral to an ovotestis are either fallopian tube or fallopian tube and vas. Fertility has been reported in patients raised as female. Testicular function tends to decline with puberty, so fertility is rare for male patients.[11]

For true hermaphrodites raised as males, the hypospadias is repaired, testicular tissue is placed in the scrotum, and ovarian tissue is removed. Testicular tumors can arise in these patients, despite a decline in function that results in the need for testosterone supplementation after puberty. Seminomas, gonadoblastomas, and dysgerminomas have been described.[12] Hermaphrodites raised as females undergo clitoroplasty, vaginoplasty, and removal of testicular tissue, but do not need estrogen supplementation. In the past, 75% of true hermaphrodites were raised as males.[1] More recently, the distribution has become 50/50,[10,13] although with the current understanding of testosterone imprinting, the proportion of patients raised as males may rise again.

Male pseudohermaphrodite

Complete androgen insensitivity

Patients with CAIS present as young girls either with a hernia or with amenorrhea. CAIS can be due to a spontaneous mutation or can be an X-linked recessive disorder. Since the androgen receptor is defective and the testes make MIS, both the wolffian and müllerian systems involute, and the upper vagina, fallopian tubes, and uterus are usually absent. The vagina is short and blind ending. Serum LH, FSH, and testosterone are all elevated, since testosterone is unable to feedback to the hypothalamus. Patients have a clearly female gender identity, presumably because they also lack androgen receptor in the brain. At puberty, the abundant testosterone is converted to estradiol, leading to normal female breast development, without pubic hair development ('hairless women'). Once the diagnosis is made, gonadectomy is recommended to prevent eventual malignant degeneration of an undescended testis, usually a seminoma[12] (Figure 68.14). If the diagnosis is made prepubertally and gonadectomy is carried out, exogenous estrogen will be required to bring on puberty. An alternative is to leave the gonads in place and remove them after puberty. Since gonadectomy is easier to perform in infancy, assists in making the diagnosis of CAIS, and eliminates the risk of tumor formation, most patients who are diagnosed prepubertally undergo an early gonadectomy. Adult patients all require estrogen supplementation. Patients are not fertile, since no uterine tissue is present. If sexual function is impaired due to the short vagina, a substitution, skin flap, or Frank (dilatation) vaginoplasty can be carried out.[14]

Figure 68.14 Complete androgen insensitivity syndrome: bilateral inguinal explorations revealed apparently normal testes.

Partial androgen insensitivity

Patients with partial loss of androgen receptor activity were previously diagnosed with Reifenstein syndrome, Lub's syndrome, or Gilbert–Dreyfus syndrome, which are now categorized as PAIS. Phenotypically, the genitals range from mildly virilized to fully male. There is no pathognomonic enzyme abnormality that can be used to define PAIS. Depending on the response to testosterone stimulation, patients may be raised as male or female. The response to exogenous testosterone is not impressive.[15]

5α-Reductase deficiency

This disorder is also known as pseudovaginal perineoscrotal hypospadias. 5α-Reductase has two forms: type 1 is found in non-genital tissue and type 2 is found in the genitals. Boys with 5α-reductase type 2 deficiency have low levels of DHT, so they are born with perineal hypospadias, a blind-ending vagina, and testes that are usually palpable. At puberty, a rise in testosterone level leads to phallic enlargement due to peripheral conversion by the normal 5α-reductase type 1. Pubic hair does not develop well, and the prostate does not enlarge.[16,17] The diagnosis is made by a high testosterone: DHT ratio of 50:1, compared with the normal ratio of 5–10:1.[7] Children with this disorder in the Dominican Republic and Papua New Guinea are initially raised as females and then change their gender identity at puberty to male. There are rare reports of fertility in affected men, since most men have low-volume ejaculates. Preoperative testosterone stimulation to lengthen the penis has been used before hypospadias repair. An improved understanding of how gender identity changes during development in patients with 5α-reductase deficiency has resulted in most of these individuals being raised as males.

Persistent müllerian duct syndrome

Also known as hernia uteri inguinalis, this presents as either an undescended testis or an inguinal hernia in a boy. Lack of MIS synthesis or a defective MIS receptor is felt to be the cause. The müllerian structures (fallopian tube, uterus, and upper vagina) are intimately associated with the wolffian structures. There is no risk of malignant degeneration of the müllerian structures since there is no ovarian tissue, so excision is not necessary, and would risk injury to the vas and testis. Orchiopexy is felt to be the optimal surgical

management, since some men have had children without assisted reproductive techniques.[18] The testes are at risk for tumor formation, as are other abdominal undescended testes, so if the testis cannot be successfully placed in the scrotum for monitoring, orchiectomy should be considered.

Congenital lipoid adrenal hyperplasia

Previously thought to be due to a defect in 20,22-desmolase activity, this condition is actually due to a protein – known as steroid acute reaction protein (StAR) – controlling the metabolism of 20,22-desmolase. Patients are 46,XY, but appear as phenotypic newborn girls, and present with diarrhea, salt wasting, and shock, similar to patients with salt-wasting CAH. Their adrenals are massively distended with cholesterol, which cannot be further metabolized. They require corticosteroid and mineralocorticoid supplementation, and are usually raised as girls after the testes are removed.[19]

3β-hydroxysteroid dehydrogenase deficiency

This deficiency is discussed above in the section on the female pseudohermaphrodite, and represents the only enzymatic defect to cause genital ambiguity in both males and females.

17β-hydroxylase dehydrogenase (type 3) deficiency

This enzyme is only found in the testis. (17β-Hydroxylase dehydrogenase type 1 is responsible for catalyzing the conversion of estrone to estradiol in the ovary – see Figure 68.6.) Since androstenedione cannot be converted to testosterone and DHT, the external genitalia do not masculinize in 46,XY infants. However, androstenedione is able to keep the wolffian duct from involuting. The perineum is female, with clitoral hypertrophy and a short vaginal pouch. Most patients are Palestinians living in Gaza. The diagnosis is made by an elevated androstenedione/testosterone level. At puberty, increased peripheral (non-testicular) conversion of androstenedione to testosterone results in virilization, and patients change their gender identity from female to male, similar to patients with 5α-reductase deficiency.[20]

17α-Hydroxylase/17,20-lyase deficiency

Females with this disorder have mild clitoral hypertrophy, whereas males have hypospadias. The distinguishing factor is the presence of hypertension, since the pathway is directed toward aldosterone synthesis. Progesterone, deoxycorticosterone, aldosterone, and progesterone/17-hydroxyprogesterone ratio are elevated.[21]

Mixed gonadal dysgenesis

Mixed gonadal dysgenesis is the second most likely diagnosis in a newborn with ambiguous genitalia. Patients have a 45,XO/46,XY karyotype, and present with hypospadias and one palpable gonad (Figure 68.15). Gonadal exploration in the patients with ambiguous genitalia shows a streak gonad and ipsilateral unicornuate uterus, and occasional wolffian structures. The contralateral gonad may be a normal or dysgenetic testis. Müllerian structures can also be found ipsilateral to the testis. Streak gonads and dysgenetic testes are removed, and normal testes are placed into the scrotum (Figures 68.16–68.18).

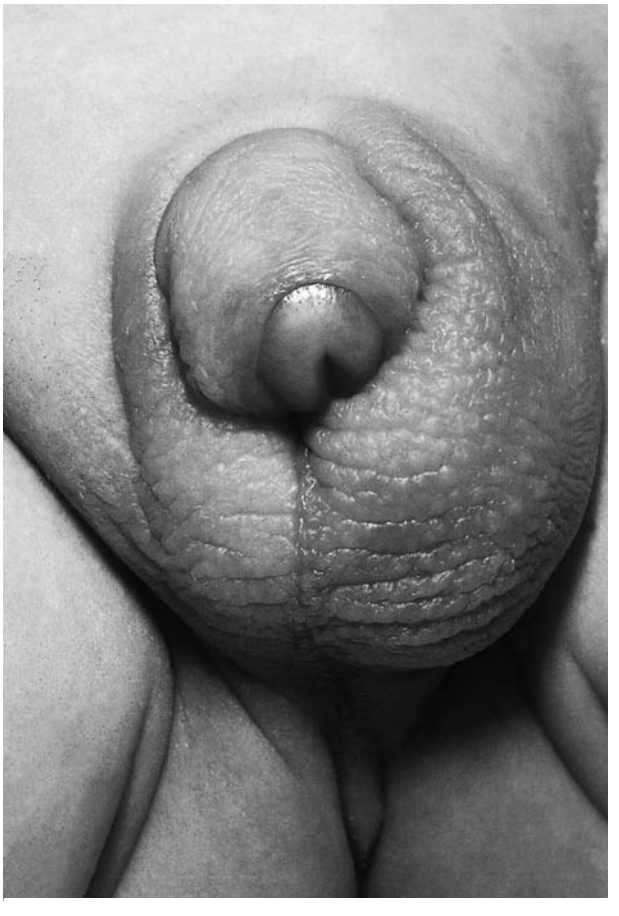

Figure 68.15 Mixed gonadal dysgenesis, showing a flat and empty right hemiscrotum in a boy with hypospadias.

Figure 68.16 Mixed gonadal dysgenesis, postpubertal. Enlarged clitoris. (Reproduced from Snyder,[4] with permission.)

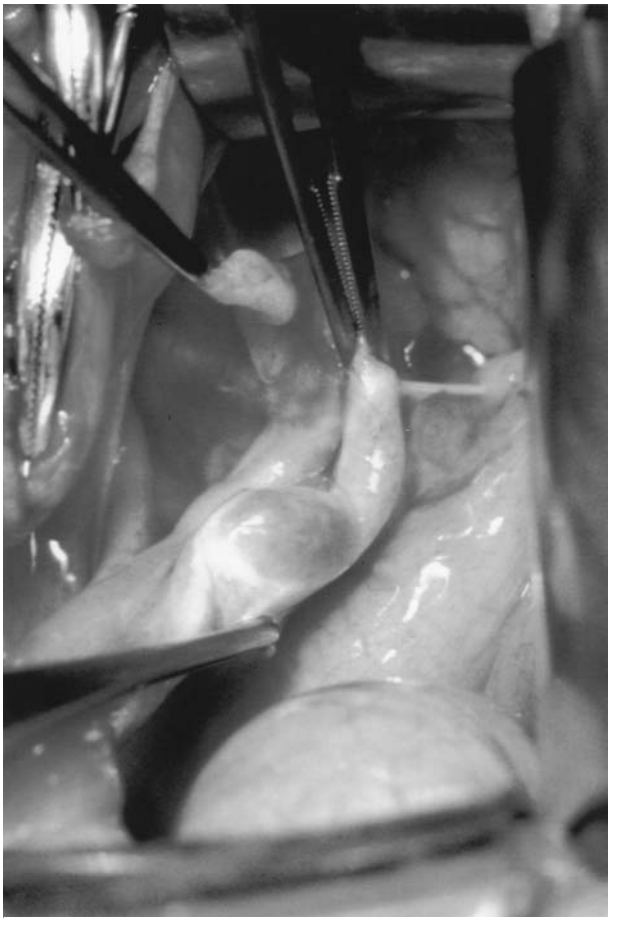

Figure 68.17 Mixed gonadal dysgenesis. Left intra-abdominal testis was removed. (Reproduced from Snyder,[4] with permission.)

Patients are at risk for developing gonadoblastomas, dysgerminomas, and seminomas in the testes. A renal ultrasound is helpful to rule out renal masses if the clinical diagnosis of Denys–Drash syndrome is made (Wilms' tumor, renal failure, ambiguous genitalia.) Testosterone is required after puberty, and patients are usually infertile. If the patient is well virilized, he is usually raised as a male, and the hypospadias is repaired.

Turner's syndrome and pure gonadal dysgenesis

Patients with a 45,XO or 45,XO/46,XY karyotype present with a combination of webbed neck, shield chest, aortic coarctation, horseshoe kidney, and short stature, known as Turner's syndrome. Only 5% have a 45,XO/46,XY karyotype.[22] Both gonads are streaks and are not at risk for tumor unless they are mosaic with 45,XO/46,XY. Because of their characteristic physical findings, these patients are not encountered in the newborn period as intersex patients. Growth hormone and estrogen supplementation are generally required. Patients with gonadal dysgenesis can also have 46,XX and 46,XY karyotypes. Although they are normal phenotypic females without Turner's stigmata and have fallopian tubes and a uterus, the 46,XY patients (Swyer syndrome[23]) are at risk for developing gonadoblastoma, and should have their gonads removed (Figure 68.19).

Gender identity and role: choosing the sex of rearing

The relative importance of environment vs genetics on gender identity has been vigorously debated. The pendulum has swung from believing that gender identity was entirely determined by environment to understanding that both genetics and environment influence ultimate gender identity. In making the

Figure 68.18 Mixed gonadal dysgenesis. Right streak gonad was removed, and cycling with estrogen and progesterone begun. (Reproduced from Snyder,[4] with permission.)

decision regarding gender assignment, the following factors should be considered if the 'optimal gender policy' is followed: possible fertility, sexual function, and stable gender identity.[24,25] Whereas fertility is fairly well understood, the data on eventual sexual function are sparse,[26–28] and understanding gender identity long term is even more difficult to predict. Unfortunately, it is difficult to correlate genital virilization with gender identity.

Testosterone undoubtedly 'imprints' the prenatal brain, and the highly publicized cases of gender reassignment have involved genotypic and phenotypic males reassigned as females. Patients choose to identify as male or female (gender identity) and also behave in different ways (gender role) depending on which sex they identify with. Severely virilized CAH patients are more likely to change gender identity later in life, and less significantly affected patients show a more 'tomboyish' gender role than control patients.[29,30] Advocacy groups such as the Intersex Society of North America propose that surgery should be delayed until patients can make the choice for themselves.[31] There is no argument that patients should be assigned a male or female gender at birth. The controversy is over the timing and necessity of genital surgery, which hopefully will become clearer once long-term data on gender identity and gender role are accumulated.[32–34]

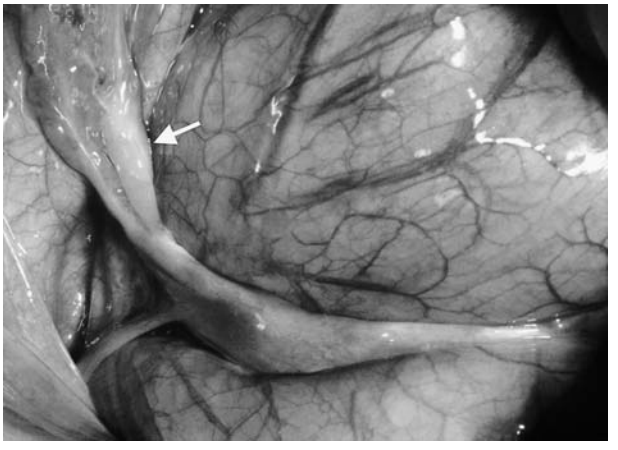

Figure 68.19 XY gonadal dysgenesis: the streak gonad on the left broad ligament (arrow) showed a few testicular elements on microscopy.

Key points

1. Internal genital development depends on the ipsilateral gonad.
2. External genital development depends on the presence of testosterone and DHT.
3. A palpable gonad is usually a testis.
4. Preliminary diagnosis of CAH can usually be made based on physical examination and pelvic ultrasound.
5. There is evidence that testosterone imprints the brain prenatally.

Introduction

The pediatric urologist must be familiar with the management of anorectal malformations (ARMs) and cloacal malformations (CMs). ARMs are commonly associated with surgically relevant urinary tract and vaginal pathology. The pediatric urologist is responsible for the management of these defects. Because these malformations are relatively uncommon, it is vitally important for the reconstructive surgeon to be familiar with the embryology, anatomy, and pathophysiology of each of these. Considerable morbidity ensues if the surgeon fails to manage these defects in a thoughtful, deliberate manner. A multidisciplinary approach to children with complex cloacal malformations is appropriate and involves pediatric general surgeons, pediatric urologists, pediatric anesthesiologists, and pediatric radiologists.

Anorectal malformations occur in approximately 1 in 4000 to 1 in 5000 live births.[1] Cloacal anomalies occur in 1 in 50 000 live births.[2] The incidence of mortality with ARMs has dropped dramatically over time. The morbidity associated with these anomalies is extensive and includes psychosocial developmental disorders, fecal incontinence, urinary incontinence, urinary tract infection (UTI), impaired intercourse, impaired fertility, as well as other abnormalities such as limb anomalies, vertebral anomalies, neurologic deficits, and tracheoesophageal fistulae.

The history of imperforate anus management dates back to the 7th century, where the earliest reports of survival with surgery (rupture of an obstructing anal membrane) may be found. In 1835, Amusset performed a perineal proctoplasty. In the 1850s, various authors reported the use of colostomy, which opened the door for successful management of high ARM. An abdominal–perineal pull-through procedure was undertaken in the 1880s[3,4] and advanced further by Rhoads et al.[5] In 1953, Stevens promoted a direct sacral approach to reconstruction, and in 1967, Kiesewetter combined these approaches into a two-stage sacroabdominoperineal pull-through procedure. Peña and Hendren ushered in the modern era of ARMs as well as cloacal management. They performed their posterior sagittal approach for the treatment of these malformations initially in 1980 and reported the results soon thereafter.[6]

Surgeons recognized the frequent association of urologic abnormalities with ARMs.[7–11] Similar recognition of the high incidence of spinal cord abnormalities, including occult spinal dysraphisms such as tethered cord, lipomas, neurenteric cysts, and diastematomyelia, advanced the management of these patients.[12–15] Patients with ARMs frequently require complex urinary reconstruction, for which unique concerns must be addressed.[16]

The development of the Malone antegrade continence enema or continent cecostomy[17] advanced the management of fecal incontinence and fecal retention in children with neurologic conditions such as myelomeningocele. Surgeons now successfully apply this procedure to enable fecal undiversion in children with ARMs who have previously undergone colostomy for refractory fecal incontinence.[18–19]

Spectrum of abnormalities encountered

We now know that urinary, genital, and anorectal development are intimately interconnected. As early as 1829, Mayer recognized an association between vaginal agenesis and other congenital anomalies.[20] Küster and Rokitansky independently confirmed this observation.[21,22] Hauser and Schreiner[23] emphasized the association of vaginal agenesis with skeletal and renal anomalies. Thus, the final association became known as the Mayer–Rokitansky–Küster–Hauser syndrome. Upper tract anomalies are encountered in

approximately one-third of these patients, mostly consisting of renal agenesis, renal ectopia, and renal fusion anomalies.[24,25] Frequent skeletal anomalies were also noted, many of which involved abnormal cervical and thoracic somite development. Duncan et al[26] referred to this as the MURCS association: müllerian duct aplasia, renal aplasia, and cervicothoracic somite association.

Similar to those observations associated with vaginal agenesis, repetitive patterns of anomalies were seen with anorectal anomalies.[27–37] This constellation originally became known as the VATER association: vertebral, anorectal, tracheoesophageal, and radial. Later, it was expanded to the VACTERL association: vertebral, anorectal, cardiac, trachoesophageal, radial/renal, and limb.

The presentation of patients with ARM and cloacal malformations varies. Some children present with an abnormal antenatal sonogram demonstrating renal anomalies, associated myelomeningocele, hydrocolpos, or exstrophy. Most frequently, patients present with an abnormal neonatal examination. In general, this consists of an absent perineal orifice, most commonly anus, occasionally vagina, or both. An abdominal mass may be present, often from hydrometrocolpos, urinary retention, or hydronephrosis. In addition, an interlabial mass may allow detection of hydrometrocolpos. Patients may fail to evacuate feces or urine, leak urine, or may have a UTI. Older children may fail to menstruate or complain of abdominal pain and have an abdominal mass from obstructed menstrual flow.

It is not surprising that an anatomic area of such complex anatomy as the perineum, which develops over such a brief duration, would have a high incidence of congenital anomalies.

Table 69.1 outlines common female congenital anomalies involving the urethra, vagina, and rectum. Common anorectal abnormalities include anal stenosis, ectopic anus, covered anus, imperforate anus (high or low), and atresia. Many vaginal anomalies may be associated with anorectal malformation in girls, including congenital vaginal obstruction, vaginal agenesis, and duplication anomalies. Urogenital sinus malformations (UGSMs) involve both the female urethra and vagina and may or may not occur in the setting of intersex. A commonly associated vaginal and anorectal abnormality is that of imperforate anus with fistula to the vestibular or vaginal regions. Rarely, a fistula without imperforate anus is present. Cloacal anomalies and cloacal exstrophy represent anomalies that involve the urethra, vagina, and anorectum.

Table 69.1 Common female congenital anomalies

Urethra	Vagina	Anorectum
Epispadias	Congenital obstruction[a]	Stenosis
Ectopic ureterocele	Imperforate hymen	Ectopic
	Transverse septum	Covered

Fistula without imperforate anus	
Cloacal exstrophy	

[a] May be associated with anorectal malformations.

Table 69.2 outlines commonly encountered urethral and anorectal anomalies encountered in the male. As in the female, the spectrum of ARMs includes anal stenosis, ectopic anus, covered anus, imperforate anus, and anorectal atresia. Hypospadias,

urethral duplication, urethral agenesis, urethral stricture, and posterior urethral valves may all be present in association with ARMs. The urethra and rectum may be jointly involved in those patients who have imperforate anus with fistula to the bladder, prostatic urethra, or bulbar urethra. Urethral fistula without imperforate anus[38,39] occurs, but is relatively rare. As with the female, cloacal exstrophy involves a severe anomaly of development that involves the urethra and anorectum.

Embryology

The surgeon who has some knowledge of embryology, however imperfect or controversial, will be better prepared to understand the relationship of the anus and rectum to surrounding structures and to the fistulas that so frequently connect the rectum to the genitourinary system.[40]

The limited studies of both normal and abnormal human embryos compromise our understanding of the embryology of ARM. However, animal studies raise major questions regarding the current theories of ARM embryogenesis.[41] These studies suggest that the embryonic cloaca never passes through a stage that resembles the 'persistent cloaca', which is recognized clinically. This line of investigation suggests that ARMs may arise from a short cloacal membrane associated with deficient dorsal cloacal anlage. Impaired septation may not ultimately prove to be etiologic of ARMs, as classically conceptualized. Nonetheless, the classic embryologic concepts remain useful because they predict human disease patterns.[42,43] Figure 69.1 depicts a classical approach to the embryologic derivation of the rectum, anus, vagina, and urethra. The closing plate of the cloaca (the cloacal membrane) is composed of only two layers, the endoderm and ectoderm, in immediate apposition (see Figure 69.1a). The urorectal septum (see Figure 69.1b) functions as a mesodermal tissue

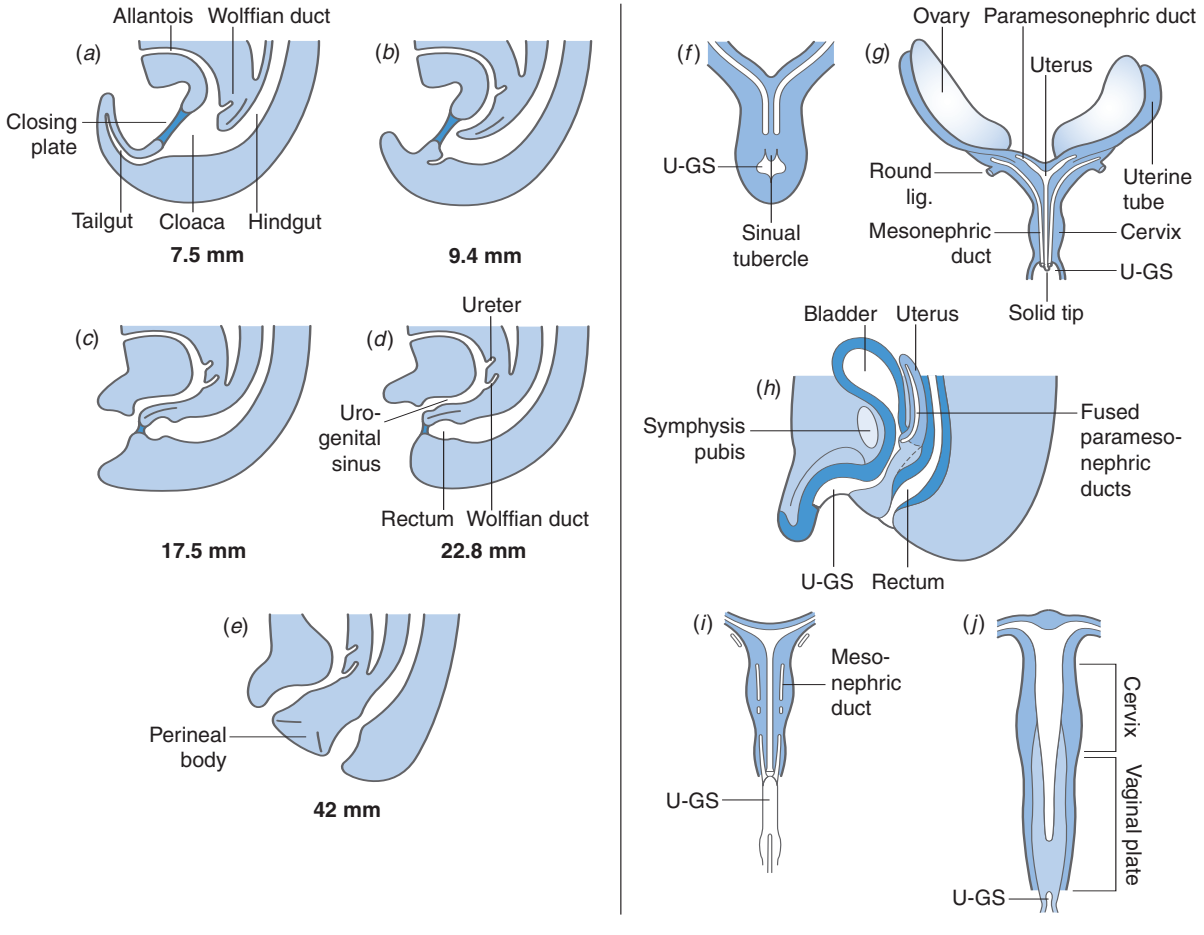

Figure 69.1 Embryology of cloacal and urogenital development. U-GS = urogenital sinus. (From O'Raholly and Muller[42] and Skandalakis et al.[45])

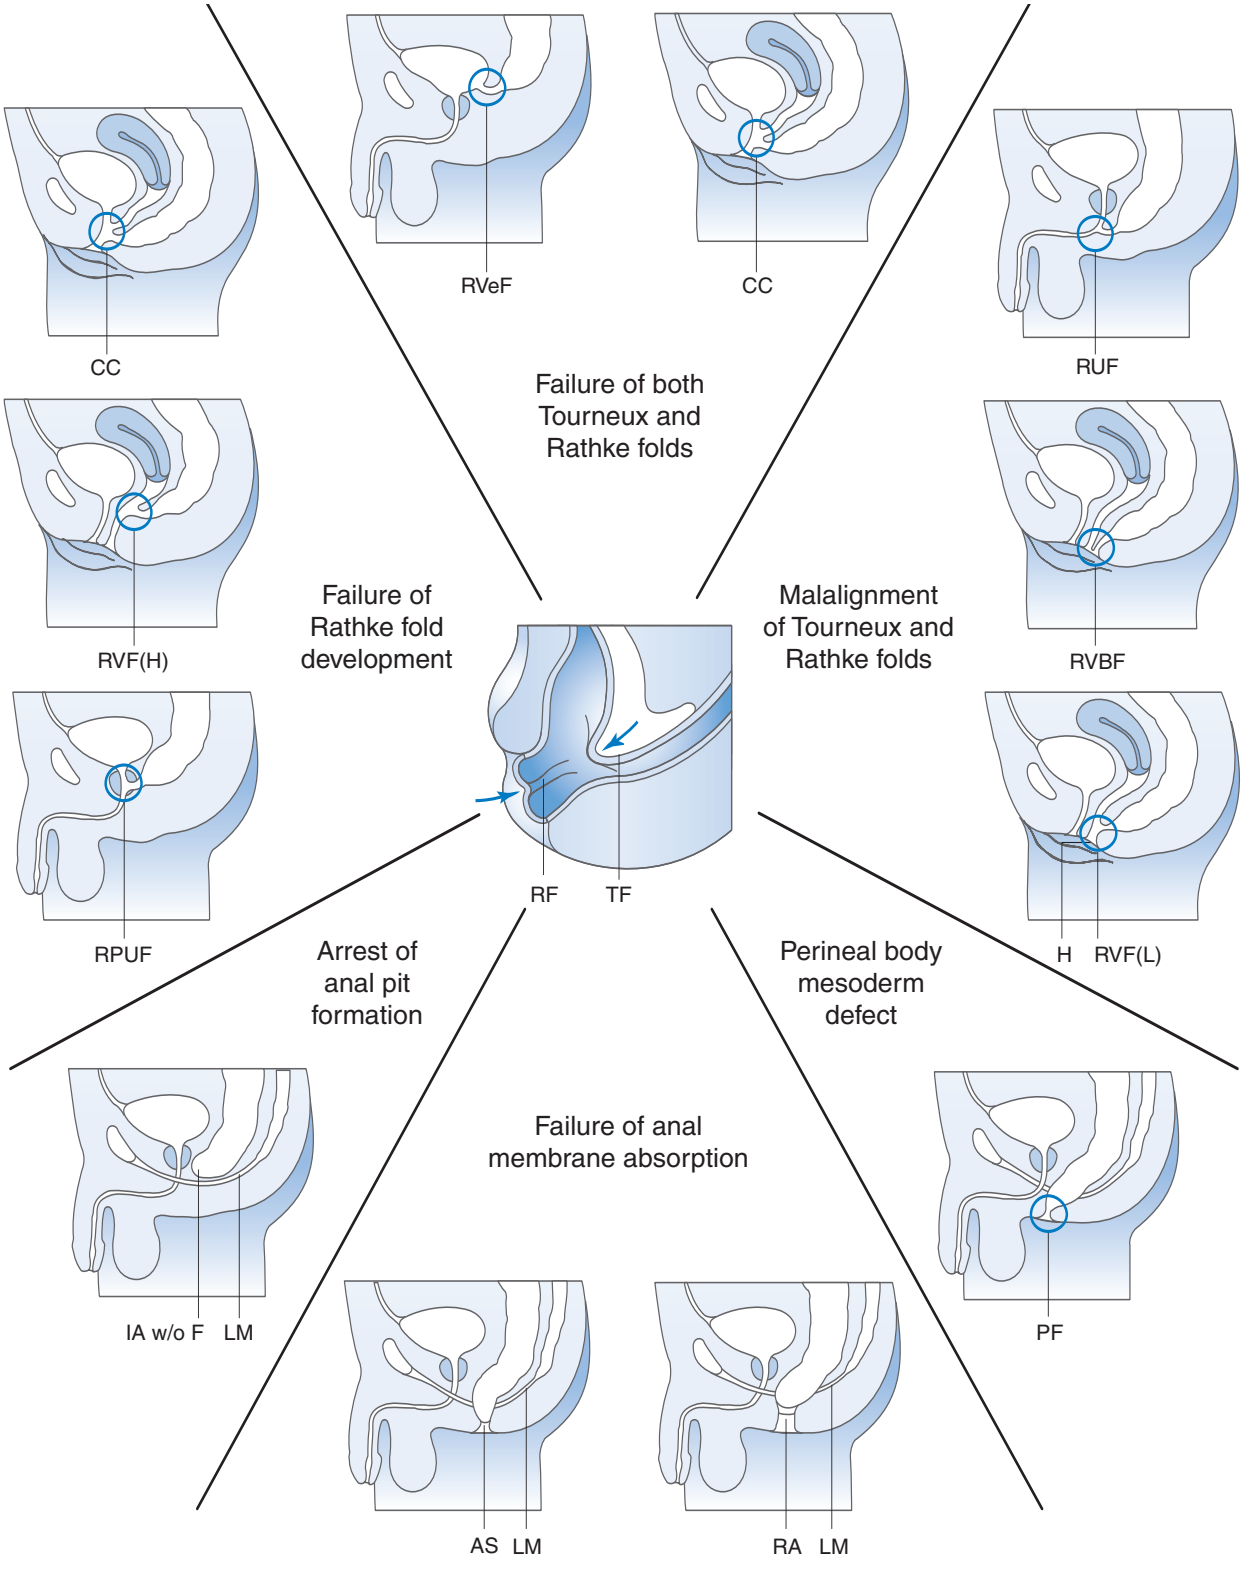

Figure 69.2 Spectrum of anomalies associated with imperforate anus. AS = anal stenosis; CC = common cloaca; IA w/o F = imperforate anus without fistula; RF = Rathke fold; RA = rectal atresia; RPUF = rectoprostatic urethral fistula; RUF = rectourethral fistula; RVF(H) = rectovaginal fistula (high); RVF(L) = rectovaginal fistula (low); RVeF = rectovesical fistula; RVBF = rectovestibular fistula; TF = Tourneux fold; LM = levator muscle; PF = perineal fistula; H = hymen. (Redrawn after Paidas and Peña.[45])

wedge, the medial portion of which (Tourneux fold) is progressively driven caudally toward the cloacal membrane by progressive fusion of the lateral ridges (Rathke folds) which grow inward from the sides of the cloaca. The urorectal septum divides the cloacal membrane into the urogenital membrane and the anal membrane, which subsequently ruptures (see Figure 69.1c,d). Differential growth causes the anal membrane to be displaced caudally and depressed below the surface, forming the anal pit. The pectinate line in the fully developed human represents the level of the anal membrane. Further differential growth separates the urogenital and anal orifices with the formation of the perineal body (see Figure 69.1e).

Paidas and Peña offer an alternative explanation of various ARMs, as outlined in Figure 69.2.[45] In this scheme, failure of the Rathke fold (RF) development results in the rectoprostatic urethral fistula (RPUF) in males, and the high rectovaginal fistula (RVFH) and common cloaca (CC) in females. Similarly, failure of both Rathke and Tourneux fold (TF) development results in the rectovesical fistula in males and common cloaca in females. Malalignment of Tourneux and Rathke folds causes rectourethral fistulae (RUF) in males and rectovestibular (RVBF) and low rectovaginal fistulae (RVFL) in females. A mesodermal defect at the level of the perineal body results in perineal fistulae (PF). Partial or complete failure of anal membrane absorption results in anal stenosis (AS) or rectal atresia (RA), respectively. The arrest of the anal pit formation results in imperforate anus without fistula, while abnormal fusion of the genital folds gives rise to the covered anus.

The developing mesonephric duct induces the formation of the paramesonephric ducts, which arise as coelomic invaginations.[42] The paramesonephric ducts grow caudally to insert into the urogenital sinus. Caudally, they fuse to become the uterus, while cranially the unfused portions become the uterine or fallopian tubes. A sinual tubercle develops at the site of insertion of the solid tip of the paramesonephric duct and the urogenital sinus (see Figure 69.1f–h). This intimate embryologic relationship between the mesonephric and paramesonephric ducts explains the high incidence of upper tract urinary anomalies encountered with anomalous vaginal development.

The vaginal plate occludes the developing vagina (see Figure 69.1i). With differential growth, the vagina elongates and slides caudally down the dorsal surface of the urethra to establish a separate vestibular opening, as the vaginal plate desquamates to create the vaginal lumen. The hymen represents the junction of the sinual tubercle and the urogenital sinus. Failure of the hymen to rupture (imperforate hymen) and failure of vaginal plate canalization (vaginal atresias and vaginal septa) may cause hydrocolpos (obstructive fluid distention of the vagina) or hydrometrocolpos (obstructive fluid distention of both the vagina and uterus). After menarche, vaginal obstruction may result in hematocolpos or hematometrocolpos (obstructive distention with blood). Müllerian (or uterine) aplasia represents absence of the uterus and results from inadequate caudal progression of the developing paramesonephric ducts. Here, the distal most vagina, ovaries, and external genitalia are normal. A unicornuate uterus occurs from developmental failure of one paramesonephric duct, while uterus didelphys (two uteri, two cervices, and two vaginas), uterus duplex bicollis (two uteri, two cervices, and one vagina), and uterus duplex unicollis or bicornuate uterus (two uteri, one cervix, and one vagina) arise from various degrees of failure of paramesonephric duct fusion.

Anomalies of anorectal development: imperforate anus

Imperforate anus exists as a large spectrum of anomalies. For this reason, classification systems are essential. Stephens and Smith[46] presented a classification

Table 69.3 Wingspread classification of anorectal malformations

Female	Male
High	**High**
Anorectal agenesis	Anorectal agenesis
Rectovaginal fistula	Rectoprostatic fistula
No fistula	Rectovesical fistula
Rectal atresia	No fistula
	Rectal atresia
Intermediate	**Intermediate**
Rectovestibular fistula	Rectobulbar fistula
Rectovaginal fistula	Anal agenesis without fistula
Anal agenesis without fistula	
Low	**Low**
Anovestibular fistula	Anocutaneous fistula
Anocutaneous fistula	Anal stenosis
Anal stenosis	Rare malformations
Cloaca	
Rare malformations	

After Stephens and Smith.[46]

Table 69.4 Incidence of anorectal anomalies

Male		Female		Total
High (35%)		High (13%)		High (26%)
Rectourethral fistula	81%	Cloaca	86%	
Rectovesical fistula	10%	Anorectal agenesis without fistula	5%	
Anorectal agenesis without fistula	8%	Rectovaginal fistula	5%	
Rectal atresia	1%	Rectovesical fistula	2%	
		Rectal atresia	2%	
Intermediate (14%)		Intermediate (7%)		Intermediate (11%)
Rectobulbar fistula	56%	Rectovestibular fistula	54%	
Anal agenesis without fistula	38%	Anal agenesis without fistula	21%	
Anorectal stenosis	7%	Rectovaginal fistula	20%	
		Anorectal stenosis	5%	
Low (49%)		Low (72%)		Low (58%)
Anocutaneous fistula	65%	Anovestibular fistula	42%	
Covered anal stenosis	21%	Anocutaneous fistula	30%	
Covered anus	14%	Anovulvar fistula	17%	
		Covered anus	6%	
		Covered anal stenosis	4%	
		Other	1%	
Miscellaneous (2%)		Miscellaneous (8%)		Miscellaneous (5%)

From Endo et al.[47]

for anal rectal malformations, outlined in Table 69.3. This classification is detailed and anatomically precise. A study of 1992 patients with ARMs from Japan[47] demonstrated the incidence of these anomalies (Table 69.4). 'Low' lesions represented 58% of patients; 'high' and 'intermediate' lesions were found in 26% and 11% of patients, respectively. Only 13% of female ARMs were classified as 'high', most of which were CMs. In contrast, 35% of males had 'high' lesions, 81% of whom had rectourethral fistulae. 'Low' lesions occurred in 49% and 72% of males and females, respectively, most of which were anocutaneous or anovestibular fistulae. 'Intermediate' lesions are less common but important because they are managed as high lesions but appear to be low lesions on examination. Brock and Peña[37] promoted a classification system that is useful clinically (Table 69.5), dividing both males and females into those for whom no colostomy is required, for whom colostomy is required, and complex malformations. In both males and females, those patients for whom no colostomy is required represent a rather simple spectrum of ARMs. In contrast, those patients requiring colostomy represent a more diverse population of patients with more difficult anatomic problems.

Table 69.5 Peña classification of anorectal malformations and fistulae

Female	Male
No colostomy required	No colostomy required
Rectoperineal (cutaneous) fistula	Rectoperineal (cutaneous) fistula
	Anal stenosis
	Anal membrane
Colostomy required	Colostomy required
Vestibular fistula	Rectourethral fistula:
Vaginal fistula	Bulbar
Anorectal agenesis without fistula	Prostatic
Rectal atresia	Rectovesical fistula
Persistent cloaca	Anorectal agenesis without fistula
	Rectal atresia
Complex malformations	Complex malformations

From Brock and Peña.[37]

The management of the patient with imperforate anus is outlined in Figures 69.3 and 69.4. Neonatal evaluation begins with a detailed physical examination followed by a period of observation usually ranging between 18 and 24 hours. This not only enables medical stabilization and exclusion of important associated congenital anomalies but also helps in determining the level of the imperforate anus. Infants who pass meconium through the urethra or into the blad-

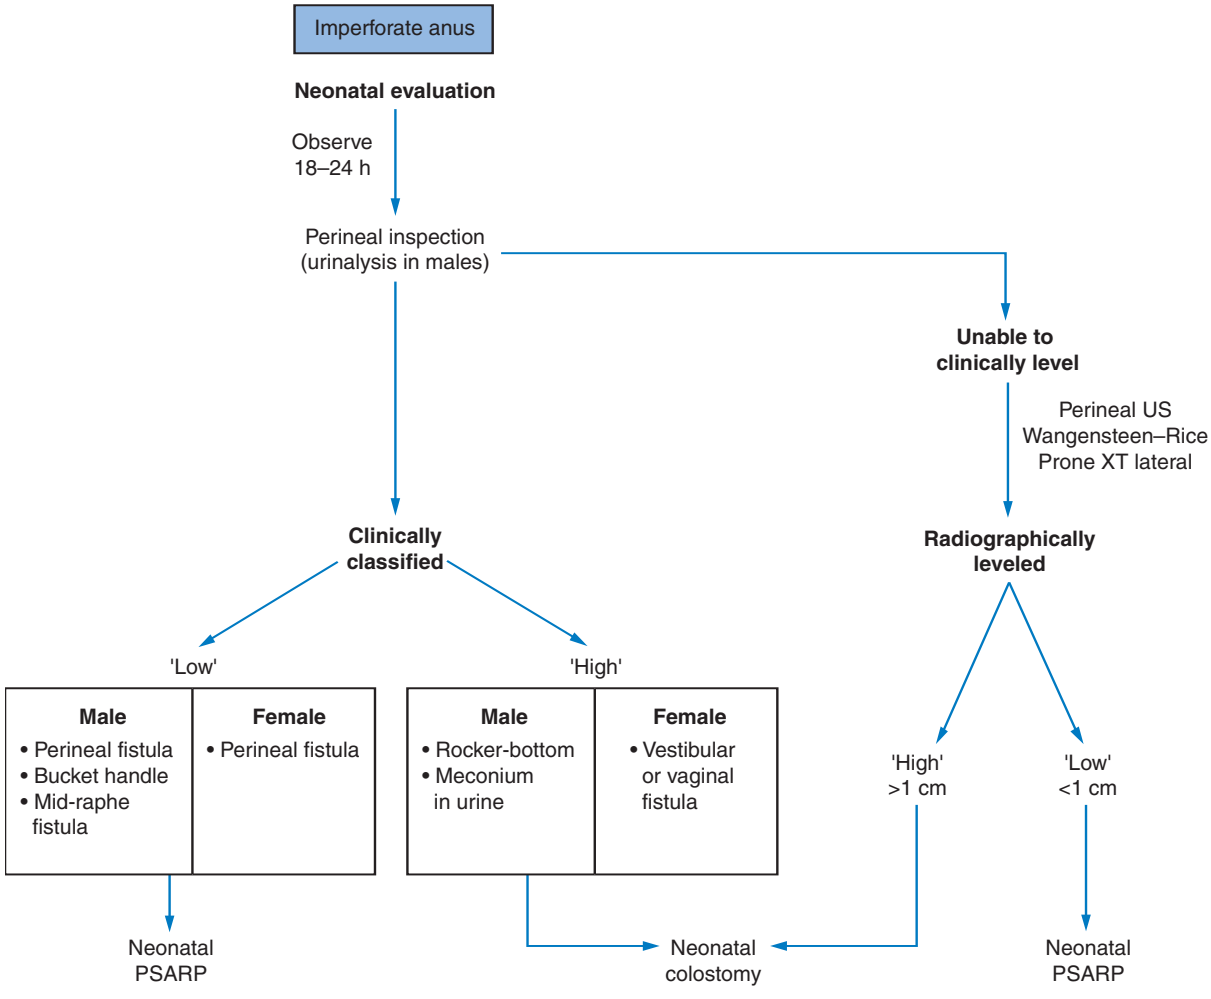

Figure 69.3 Neonatal evaluation and management of patient with imperforate anus. PSARP = posterior sagittal anorectoplasty.

der may be detected by direct inspection or by urinalysis. This indicates a high imperforate anus. In contrast, those patients who pass meconium through a perineal fistula generally have a low imperforate anus. In males, the presence of a 'bucket handle' abnormality or a mid-raphe fistula suggests a low imperforate anus. As noted in Figure 69.3, children with a 'rocker-bottom' anomaly or females with rectovestibular or rectovaginal fistulae usually have a high imperforate anus. Those patients with high lesions require neonatal colostomy, whereas those with a low lesion can be managed with a neonatal posterior sagittal anorectoplasty (PSARP).

Some patients must be clinically classified with radiographic evaluation. In these cases, a perineal ultrasound, a Wangensteen–Rice 'invertogram', or a prone, cross-table, lateral X-ray study is very helpful. Those infants with a radiographically determined distance between the rectal pouch and perineum exceeding 1 cm have high lesions and those with distances less than 1 cm have low lesions. Occasionally, contrast injected into a cutaneous or vestibular lesion may help to distinguish between an intermediate and a low lesion. Recently, magnetic resonance imaging (MRI) has been proposed as a tool for depicting the level of ARM as well as diagnosing associated anomalies of the spinal cord and urogenital system.[48]

As outlined in Figure 69.4, the goals of management in the first few years of life are to protect the upper urinary tracts, ensure low-pressure urinary drainage, normalize anorectal anatomy, and minimize any neurologic deficit that might arise from treatable spinal pathology. We evaluate all patients with an abdominal sonogram to include the kidneys, a contrast voiding cystourethrogram (VCUG), a spinal sonogram, and determination of postvoid residual volume of urine (PVR). Depending on these findings, patients occasionally require intermittent

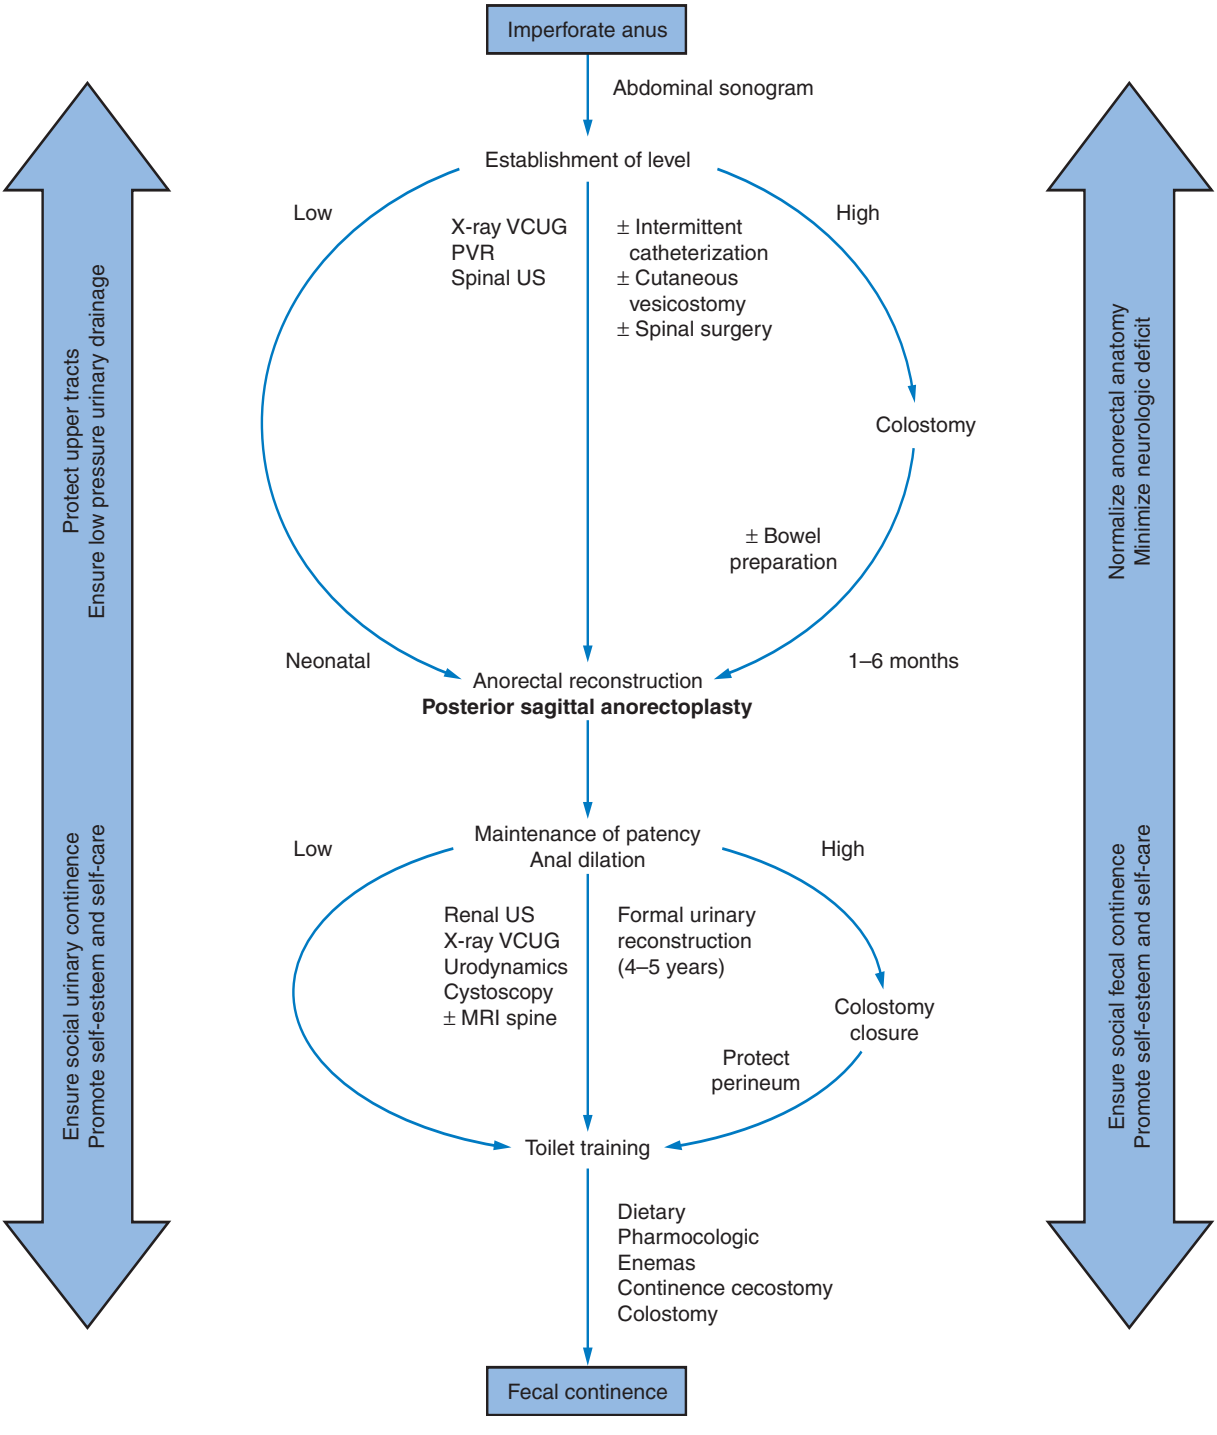

Figure 69.4 Management strategy for imperforate anus (± = possible).

catheterization, cutaneous vesicostomy, or even spinal surgery. Those patients who receive a colostomy will undergo definitive anorectal reconstruction in the form of posterior sagittal anorectoplasty (PSARP), usually between 1 and 6 months of age, but occasionally older, depending on the presence of other congenital anomalies.

The type of colostomy performed is important. Peña[49] recommends a colostomy opened at the junction of the descending colon with the sigmoid, with completely separated stomas. Transverse colostomies are difficult to clean and decompress distally, and loop colostomies are contraindicated owing to the risk of fecal contamination of the urinary tract. Figure 69.5

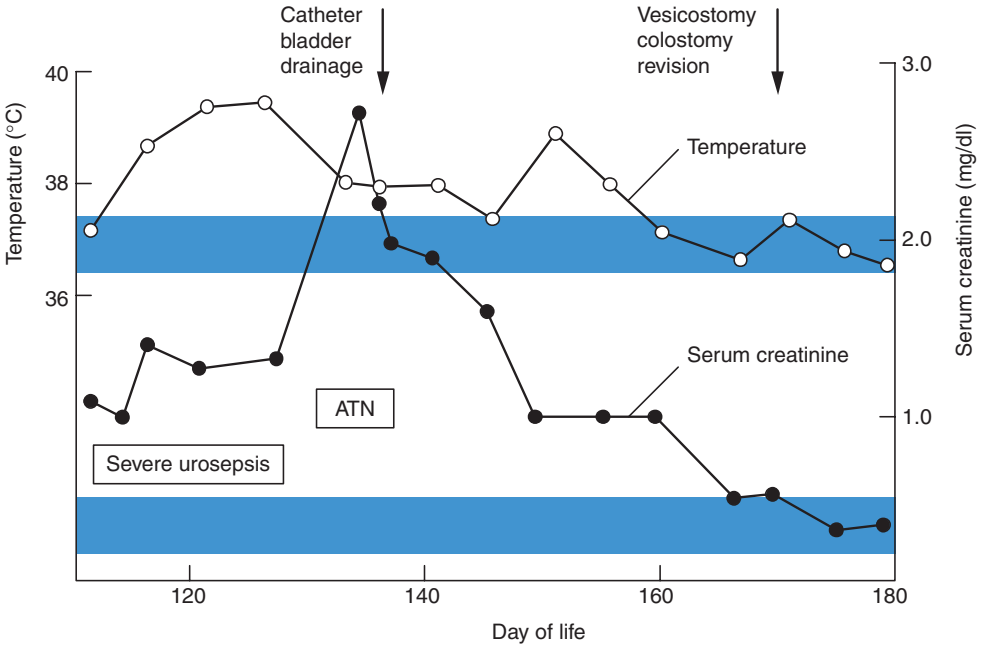

Figure 69.5 This hospital course demonstrates the sequelae of severe urosepsis in a child with imperforate anus in whom chronic urinary retention was unrecognized and a partially diverting colostomy was performed for high imperforate anus. Urosepsis persisted despite antibiotic therapy and resolved only after appropriate drainage had been instituted. (From Sheldon et al.[14])

outlines the course of an infant who received a partially diverting colostomy for high imperforate anus and who had incomplete bladder emptying. This child suffered severe urosepsis, resulting in acute tubular necrosis and significant azotemia that ultimately resolved following creation of a vesicostomy and revision of the colostomy to an end colostomy. Accordingly, patients with rectourinary fistulae, particularly, those with incomplete bladder emptying and/or vesicoureteral reflux (VUR), should be managed with a completely diverting colostomy.

As outlined in Figure 69.4, the goals of management of the preschool and school-aged child with ARMs are to ensure social urinary and fecal continence and to promote self-esteem and self-care. Following PSARP, maintenance of anorectal patency is generally ensured by gentle anal dilation. Children who have previously received a colostomy undergo colostomy closure once healing of the PSARP is complete. These children often develop a severe perineal rash owing to the sudden exposure to feces. We minimize this aggressively by applying antifungal ointment in the early post-colostomy closure period.

Children who fail to attain fecal continence are often managed by dietary or pharmacologic intervention. Occasionally, enemas may be required to achieve continence. Most effective are high cleaning enemas administered at night.[50] Frequently, the child cannot administer the enemas or enemas are not successful. In this case, the creation of a continent cecostomy for an antegrade continence enema has been helpful. This procedure creates a continent, catheterizable channel connecting the cecum and the skin. The appendix is used for this purpose most frequently; however, reconfigured ileum also works successfully. This concept was first developed and presented by Malone et al.[17] We have found this procedure effective in children who have extremely deformed and dysfunctional anal canals,[18] and it has worked even for children who had previously received colostomies for refractory fecal incontinence.

Many children have urinary tract anomalies or fail to attain urinary continence and require urinary reconstruction. They may present to the urologist for the first time after failing toilet training. These children require careful diagnostic evaluation, including renal sonogram, contrast VCUG, urodynamics, and often a cystoscopy before formal urinary reconstruction. Those who have not had previous spinal imaging require an MRI of the spine. Ultrasound evaluation of the spine after age of 6 months is unreliable because of vertebral calcification.

The surgical management of ARMs (PSARP) is illustrated in Figures 69.6 and 69.7.[45] We perform

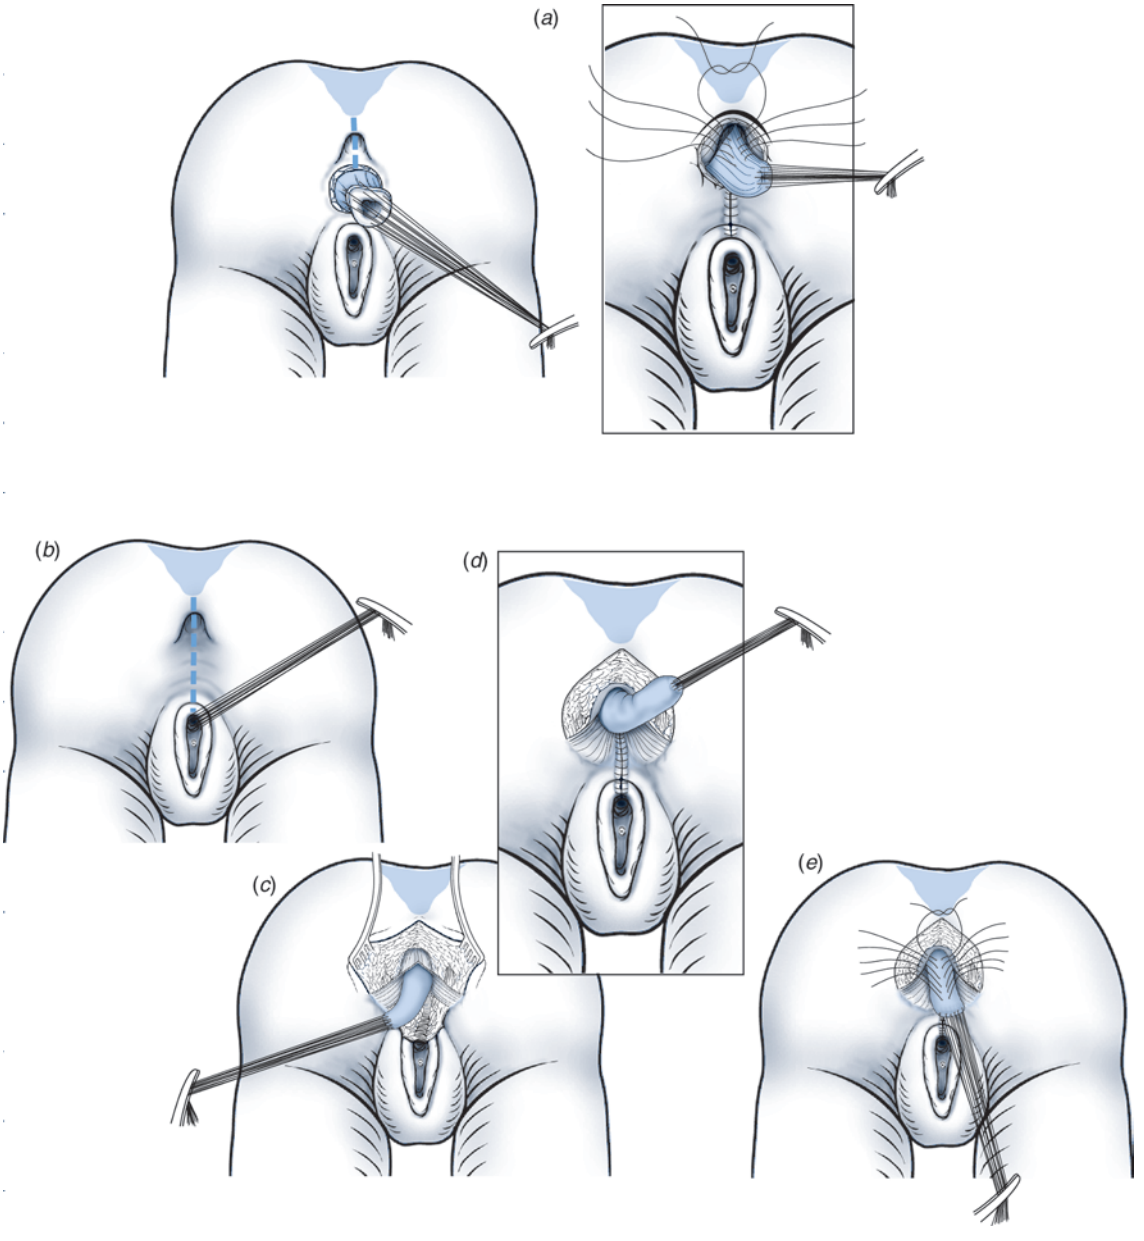

Figure 69.6 Surgical management of anorectal malformations (low lesions). See text. (Redrawn from Paidas and Peña.[45])

these procedures with the patient prone, with the pelvis elevated into a 'jack-knife' position, and with a Foley catheter indwelling. Figure 69.6 shows the approach to low lesions, as illustrated by the anoperineal fistula (see Figure 69.6a) and the anal vestibular fistula (see Figure 69.6b–e). The perineal fistula in both males and females is corrected in the newborn without a diverting colostomy. Electrical stimulation (see Figure 69.7) allows determination of the position of the anal sphincter.

The fistula is mobilized through a circumferential incision. A vertical incision is created in the posterior midline through the external sphincter mechanism, enabling the surgeon to transpose the rectum posterior to the site of the external sphincter mechanism. Similarly, the anovestibular fistula is corrected through a limited posterior sagittal approach. Many surgeons approach this in the newborn period without a protecting colostomy. Others prefer a colostomy, with early subsequent definitive correction of the anorectal malformation. In this case, the fistula is circumscribed (Figure 69.6b) and a vertical midline incision is created, extending through the sphincteric mechanism identified by electrical stimulation.

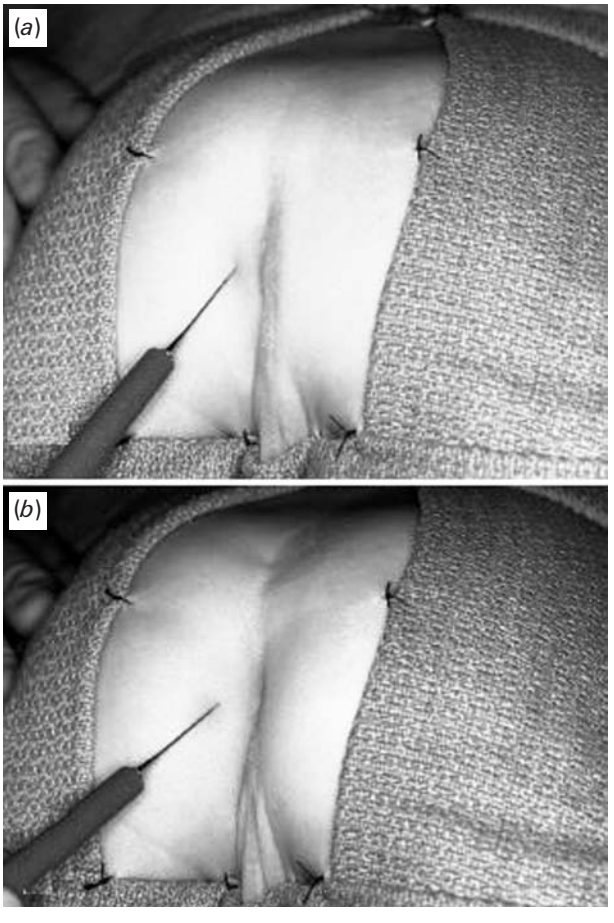

Figure 69.7 Identification of the location of the external striated muscle complex: (*a*) prior to stimulation; (*b*) during stimulation. Dimpling localizes the site of the muscle complex.

The rectum is gently dissected free from the underlying vagina to which it is intimately attached (Figure 69.6c). Once the rectum is sufficiently mobilized to prevent tension, the perineal body is reconstructed in two layers, establishing clear separation between the anus and vagina and the anterior edge of the sphincter muscle is approximated (Figure 69.6d). Posteriorly, the muscle complex is approximated and anchored to the rectum (Figure 69.6e), following which the anocutaneous anastomosis is completed.

Prior to this approach, the only access to these defects was through either the perineum, the abdomen, or a combination of the two. Surgical procedures frequently involved blind maneuvers with the consequent risk of injuring important structures. The rectum was pulled down through a path that was assumed to be the right one.[51]

We manage high lesions with a similar but more extensive approach (Figure 69.8). We illustrate this concept in a boy with a rectourethral fistula who previously had a diverting colostomy. The patient is prone with an indwelling Foley catheter. A midline incision extends from the coccyx (which is divided distally) to a point through and beyond the external sphincter (see Figure 69.8a), identified by electrical stimulation. We divide the sphincteric muscle complex and levator muscle directly in the midline, guided by electrical stimulation to minimize any resultant nerve injury. We open the rectum distally in the midline between traction sutures (see Figure 69.8b), which enables us to identify the rectourethral fistula (see Figure 69.8c,d). We place a series of traction sutures just proximal to the fistula, to help develop a plane between the rectum and the underlying urogenital structures (see Fig 69.8e–g).

Once mobilization is complete, we suture the urethral fistula closed under direct vision with the protection of an indwelling Foley catheter, making urethral injury very unlikely. We construct the perineal body in two layers and approximate the anterior edge of the external muscle complex. We approximate the levator muscle over the rectum (see Figure 69.8h), and then approximate the posterior edge of the external sphincteric muscle complex and anchor it to the rectum to prevent prolapse (see Figure 69.8i). We complete the anocutaneous anastomosis and close the posterior–sagittal incision in layers (see Figure 69.8j–k).

Urologic problems associated with imperforate anus

The incidence of structural anomalies of the urinary tract is 35% (Table 69.6). A 1987 review of 484 patients with imperforate anus detailed several critical

Table 69.6 Structural abnormalities of the genitourinary tract

Overall incidence of lesions placing both kidneys at risk = 14%.
True overall incidence of vesicoureteral reflux (patients screened by voiding cystourethrography) = 44/133 (33%).
UPJ = ureteropelvic junction.
From McLorie et al.[11]

relationships between imperforate anus and upper tract urinary anomalies (Tables 69.7 and 69.8). Fistulae connecting the rectum with the urinary tract are frequently encountered abnormalities. Excluding these, structural genitourinary anomalies occurred in 42% of patients. Non-fistula genitourinary anomalies were present in 60% of the patients with high lesions, equally in males and females and in 25% of low lesions (25% for males and 20% for females). Renal mortality occurred in 3.5% of these patients. Death from renal failure occurred in 6.4% of patients with high anorectal abnormalities (7.2% male, 3.8% female). Renal mortality occurred in only 1.1% of patients with low anorectal malformations (1.5% male, 0.8% female). This reflects the high incidence of conditions threatening both kidneys.

Table 69.8 reviews the incidence of bilateral upper tract urinary abnormalities threatening renal function. Symmetric bilateral upper tract urinary abnormalities occurred in 36 patients (7%) and included bilateral reflux, bilateral agenesis, and bilateral hypoplasia–dysplasia. Asymmetric abnormalities occurred in 32 (7%) patients. Most of these had reflux on one side and agenesis, hypoplasia–dysplasia, or obstructive pathology on the other. The overall incidence of lesions threatening both kidneys was 14%.

VUR is important in this population of children, who also frequently develop UTI and voiding dysfunction. The incidence of VUR (i.e. the incidence encountered in patients who received a screening VCUG) was 33%. The presence of a UTI in a child with imperforate anus demands prompt and aggressive evaluation and management. Epididymitis is often overlooked, and may reflect UTI in the presence of dysfunctional voiding, urethral stricture pathology, or may be associated with intermittent catheterization. Epididymitis may also be associated with ectopic ureteral insertion into the genital pathway.

The mean incidence of neurovesical dysfunction is 25% and varies quite widely among reported series (Table 69.9). As expected, high anorectal malformations have the greatest incidence. However, neurovesical dysfunction is frequently present in children with low lesions. Therefore, we screen all patients

Table 69.9 Incidence of neuropathic bladder in anorectal malformation

with ARM. As previously noted, the recognition of the high incidence of occult spinal dysraphism has had a major impact on the management of these patients.[12–14,57] Such lesions may progress following surgical correction.[57–61] Although the timing of surgical intervention remains controversial, some authors suggest that early surgical intervention results in the best functional neurologic outcome.[62]

Screening ultrasonography has proven useful in the diagnosis of occult spinal dysraphism in infants.[63,64] Older children generally require MRI for diagnosis. The significance of these dysraphic states became apparent in the early 1990s. Table 69.10 outlines an early experience, where dysfunctional voiding occurred in 31% and 5% high and low ARMs, respectively. Structural spinal cord pathology was present in 12% and 4%, respectively. One report[65] suggests that screening by MRI for occult dysraphic myelodysplasia yields an even higher incidence of spinal cord pathology. They encountered dysraphic states in 17% of low ARMs, 34% of high ARMs, 46% of cloacal anomalies, and 100% of patients with cloacal exstrophy. A recent study from Golonka et al[66] reported 27% of those with high lesions and 50% with low lesions had a tethered cord by MRI.

Some surgeons have wondered whether surgical correction of ARMs results in the development of the neuropathic bladder. Ralph et al[67] evaluated 58 patients with imperforate anus who had reached an age of ≥18 years old. Of these, 43 patients had received rectal pull-through procedures while the remainder received cutback procedures. They found evidence for a neuropathic bladder in 32 patients (55%). Ninety-one per cent of these neuropathic bladders were hyper-reflexic in nature. Thirty patients (52%) had spinal deformities, 21 (70%) of which had evidence for neurovesical dysfunction. Only three patients (5%) had hypotonic bladders, normal spinal anatomy, and high ARMs, and were felt likely to have iatrogenic neurovesical dysfunction. Boemers et al[68] evaluated 32 patients with ARMs who underwent PSARP employing urodynamic investigation. In 27 patients, urodynamic investigation was performed both before and after PSARP. No evidence of somatic nerve injury was found in this series. Detrusor failure suggestive of autonomic denervation occurred in three males, two of whom had combined PSARP with transabdominal dissection. The authors concluded that, in the absence of transabdominal dissection and significant retrovesical dissection, PSARP did not affect lower urinary tract function. De Fillipo et al[69] also reported that bladder dysfunction does not appear to follow a properly performed PSARP.

Hyperchloremic metabolic acidosis is another potential problem for these children.[70,71] This condition results from urine passing from the bladder through a rectovesical or rectourethral fistula into the defunctionalized distal limb of colon following initial diverting colostomy. The resultant absorption of urinary constituents by the bowel results in the metabolic abnormality. The occurrence of this complication requires the presence of a urorectal fistula. A long segment of defunctionalized colon (large

Table 69.10 Spinal abnormalities in patients with anorectal malformations

		Dysfunctional voiding		Structural cord lesion[a]

absorptive surface) that communicates with the fistula worsens the metabolic imbalance. Distal urinary obstruction, which may be structural (stricture) or functional (neurovesical dysfunction), also worsens this risk. UTI and renal insufficiency may also make this metabolic abnormality more likely. Creation of a low, fully diverting colostomy and ensuring effective bladder drainage helps to avoid hyperchloremic metabolic acidosis. Once established, hyperchloremic metabolic acidosis is treated by the administration of oral alkalinizing agents, intermittent catheterization, vesicostomy, or early anorectal reconstruction with division of the fistula, depending on the clinical setting.

Vaginal problems in patients with imperforate anus

Surgeons often overlook and underestimate the long-term vaginal and reproductive problems that can occur in girls with imperforate anus.[72] Whereas most girls who experience these have cloacal anomalies, these anomalies may occur in girls with imperforate anus alone. Problems may follow scarring from reconstructive vaginal surgery, from primary vaginal anomalies, such as vaginal agenesis, or from the surgical violation of the vagina in the correction of imperforate anus associated with rectovaginal fistula.

Transperitoneal pelvic surgery, needed in many of these children, may result in peritoneal adhesions that may compromise tubal function, impair fertility, and promote ectopic pregnancy. Consequently, it is imperative that the managing physician as well as the patient is aware of the potential of impaired fertility and that the surgeon ensures long-term follow-up. Some children require subsequent introital surgery to facilitate intercourse. We usually defer this surgery until adolescence.

Anomalies of both anorectal and vaginal development: cloaca

> Cloaca is the Latin word for sewer. … A persisting cloaca is normal in birds, reptiles and some fish. However, a persistent cloaca can be disastrous for the human infant if it is not managed properly.[73]

The cloaca is one of the most complex congenital anomalies for which successful restorative surgery is feasible. The approach recognizes that the cloaca represents the combination of an imperforate anus and a urogenital sinus malformation. Accordingly, all the principles already discussed in this chapter are applicable to this complex and highly heterogeneous patient population. Cloacal anatomy is sufficiently diverse to defy meaningful classification. Rather, it is best thought of as a spectrum of abnormalities occurring as a continuum, one gradually blending into the next (Figure 69.9).

From a surgical perspective, the level of insertion of the rectum is generally immaterial, as all patients are managed with an initial diverting colostomy. As with the PSARP for imperforate anus, the rectum is divided from its site of insertion and mobilized to reach the perineum. The configuration of the remaining urogenital sinus, however, has tremendous surgical implications. We manage girls with very short urogenital sinus remnants by total urogenital advancement,[75] with excellent cosmetic and functional outcome. Otherwise, the vagina is dissected away from the urogenital sinus. The urogenital sinus is closed to become the urethra and the vagina is mobilized for exteriorization. A short vagina may require interposition with a tubularized vaginal flap (most appropriate for cloaca with hydrocolpos) or a vaginal switch procedure (most applicable to patients with vaginal and uterine duplication). Occasionally, bowel interposition is necessary.

A rare (and unique) form of cloaca is the posterior cloaca.[74] Here, the cloaca drains through a posterior orifice rather than the usual anterior orifice. This draining orifice may represent a normally positioned anus. The surgical management of these infants is different from that for other cloacal anomalies.

Figure 69.10 outlines the conceptual approach to the management of cloacal malformations. During the first phase of management, the surgeon endeavors to protect the upper urinary tracts, maintain low-pressure urinary drainage, normalize the perineal anatomy, and minimize any neurologic deficit related to spinal cord anomaly. The presence of a cloacal malformation (CM) is an urgent indication for the creation of a colostomy in order to prevent fecal contamination of the urinary tract. The colostomy should be positioned well away from the lower midline abdomen, where a subsequent vesicostomy may be necessary. Contrast cystography, measurement of PVR, and spinal ultrasonography are necessary in all patients. We perform genitoscopy at the time of colostomy in selected patients, particularly those with significant hydrocolpos. Depending on the findings, intermittent catheterization, cutaneous vesicostomy, or spinal surgery may be indicated. Patients with

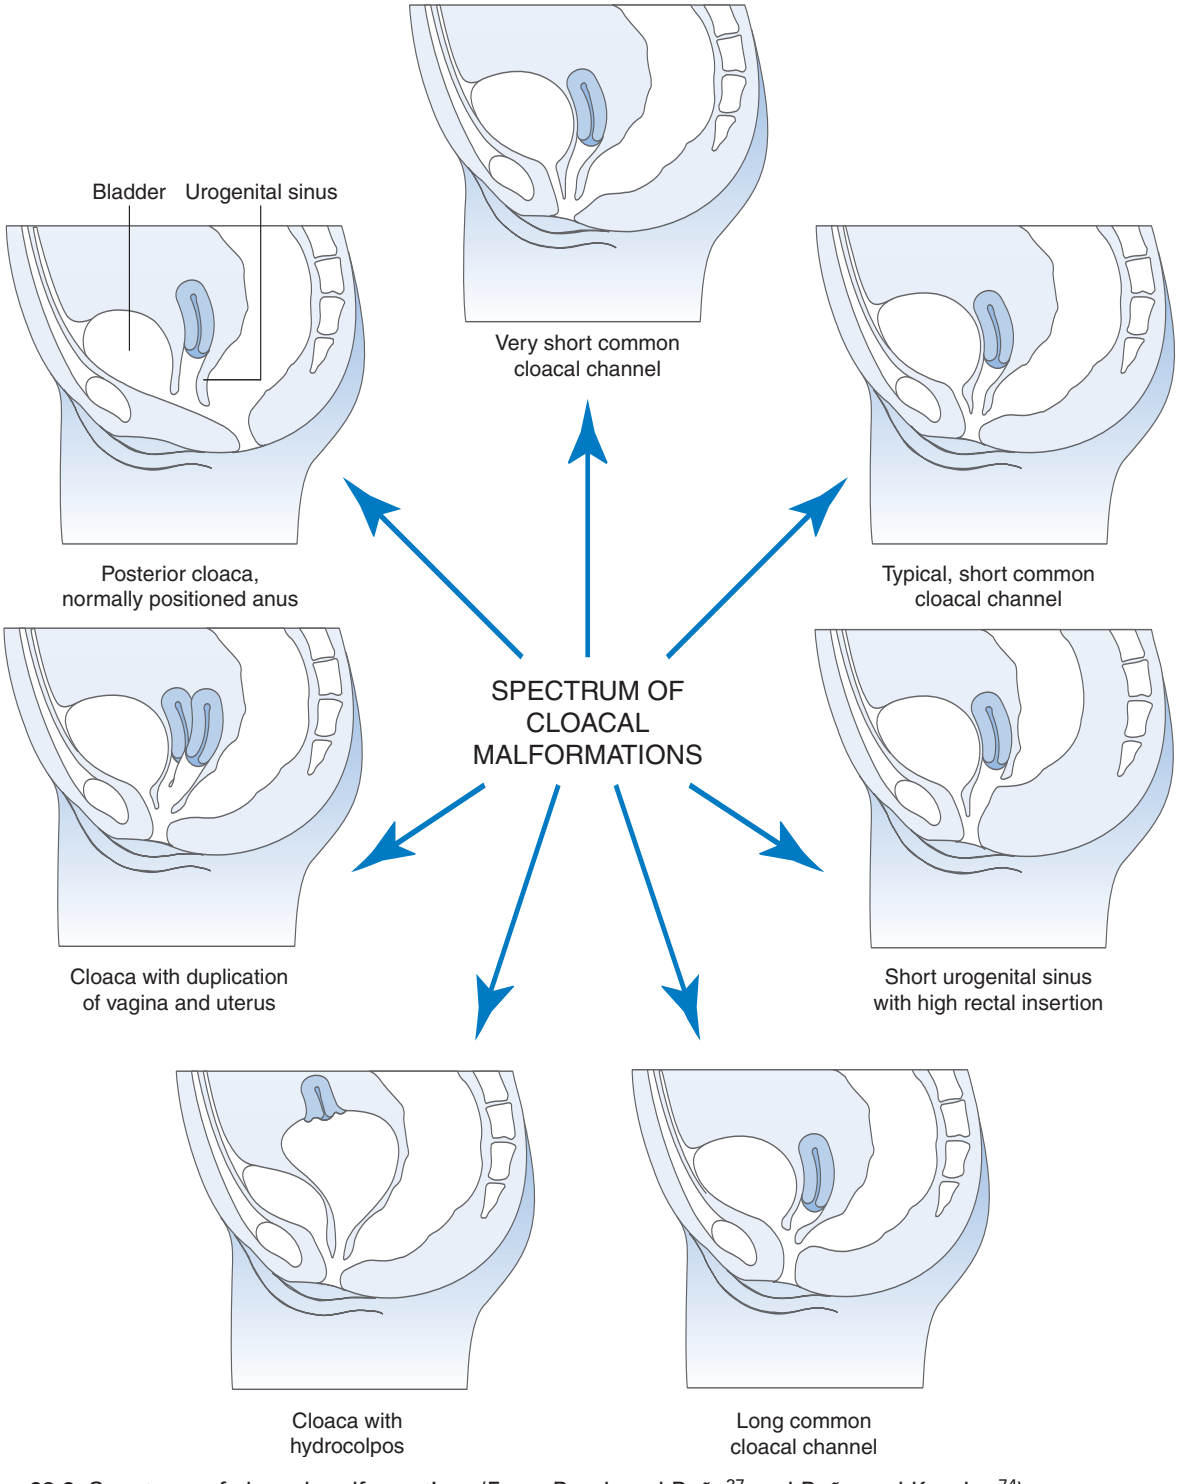

Figure 69.9 Spectrum of cloacal malformation. (From Brock and Peña[37] and Peña and Kessler.[74])

hydrocolpos require prompt and aggressive management, which may involve intermittent catheterization of the urogenital sinus and/or cutaneous vesicostomy. Rarely, cutaneous vaginostomy will be necessary.

By approximately 6–12 months of age, most patients are able to undergo posterior sagittal anorectal urethrovaginoplasty (PSARUVP) following careful bowel preparation. Patients with a low urogenital sinus abnormality undergo an advancement technique,[75] whereas those with a high urogenital sinus anomaly are managed by complete cloacal disassembly and reassembly, as described by Paidas and Peña[45] (Figure 69.11).

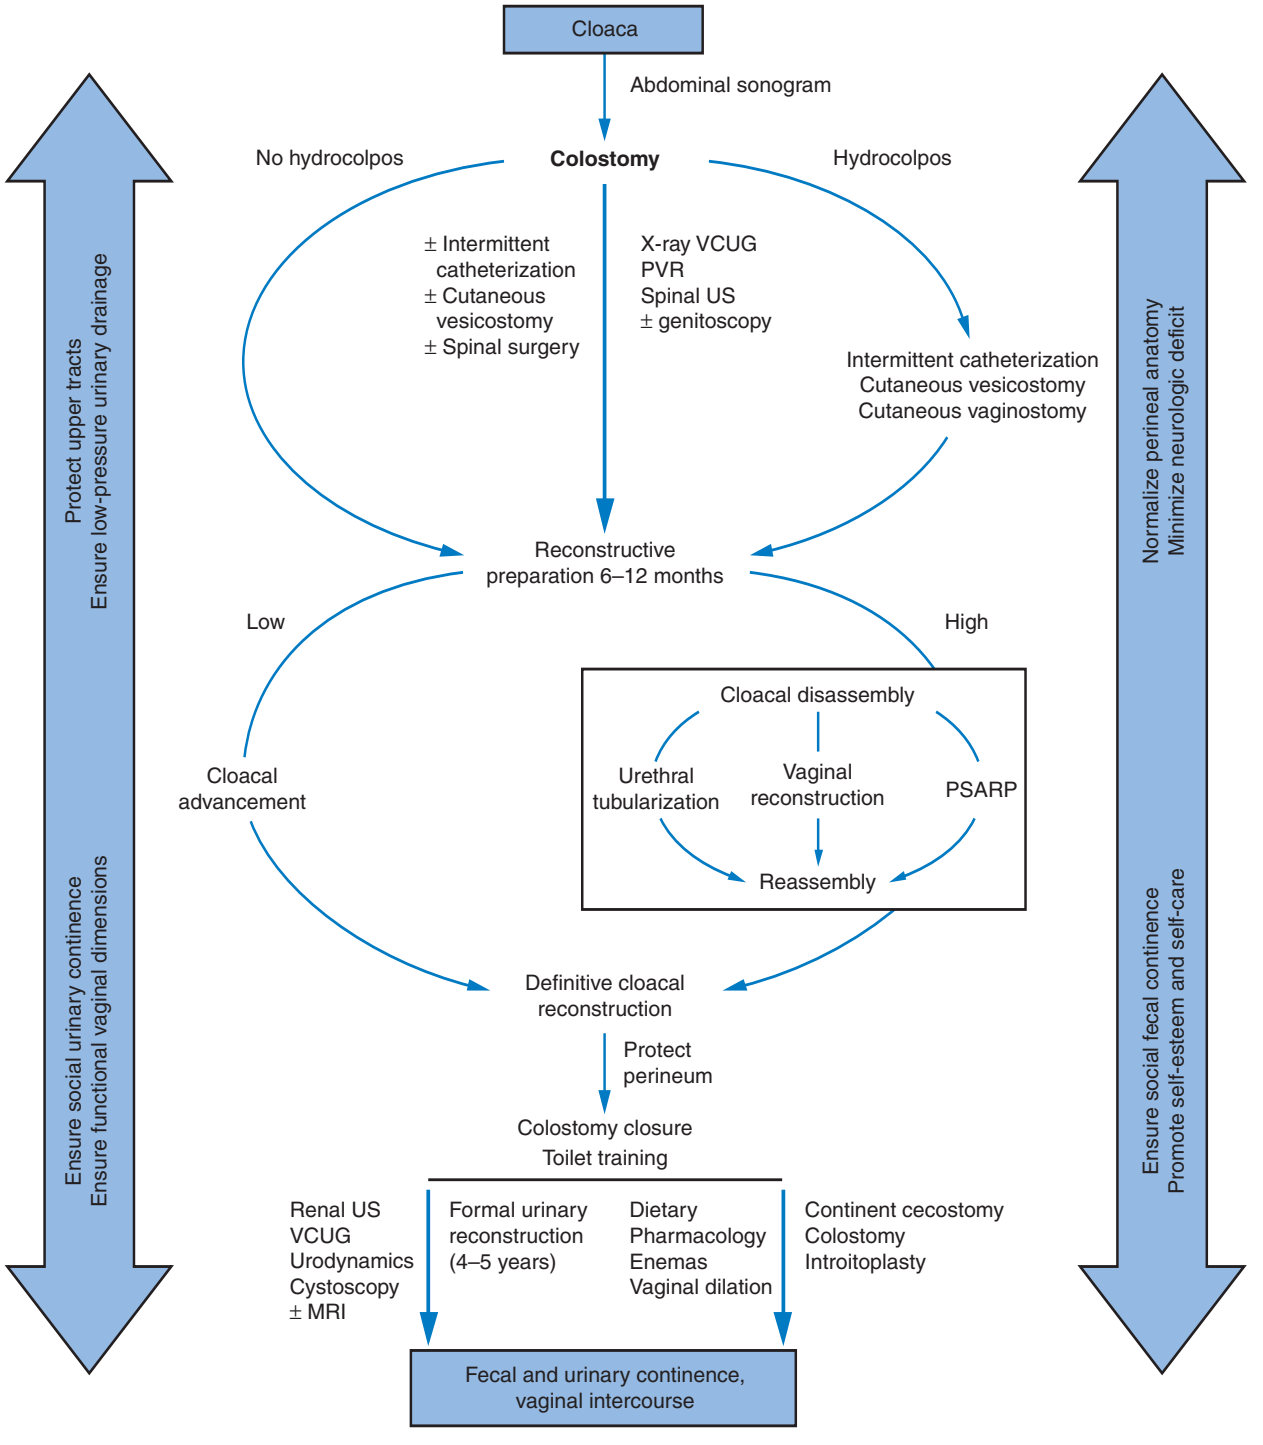

Figure 69.10 Management strategy for cloacal anomaly.

We position the patient in the prone jack-knife position, as for PSARP. The striated muscle complex is identified by electrical stimulation and we make a midline incision, this time extending from the cloacal orifice to the coccyx. The levator muscles are divided in the midline under electrical stimulation guidance. The cloaca is opened precisely in the midline, exposing the urogenital sinus, urethra, vagina, and rectum (see Figure 69.11a). A row of fine traction sutures facilitates dissection of the rectum off its attachment to the vagina (Figure 69.11b). The rectum is fully mobilized and traction sutures are placed in the vagina. The vagina is carefully dissected off the urethra, which is difficult because of the dense adherence

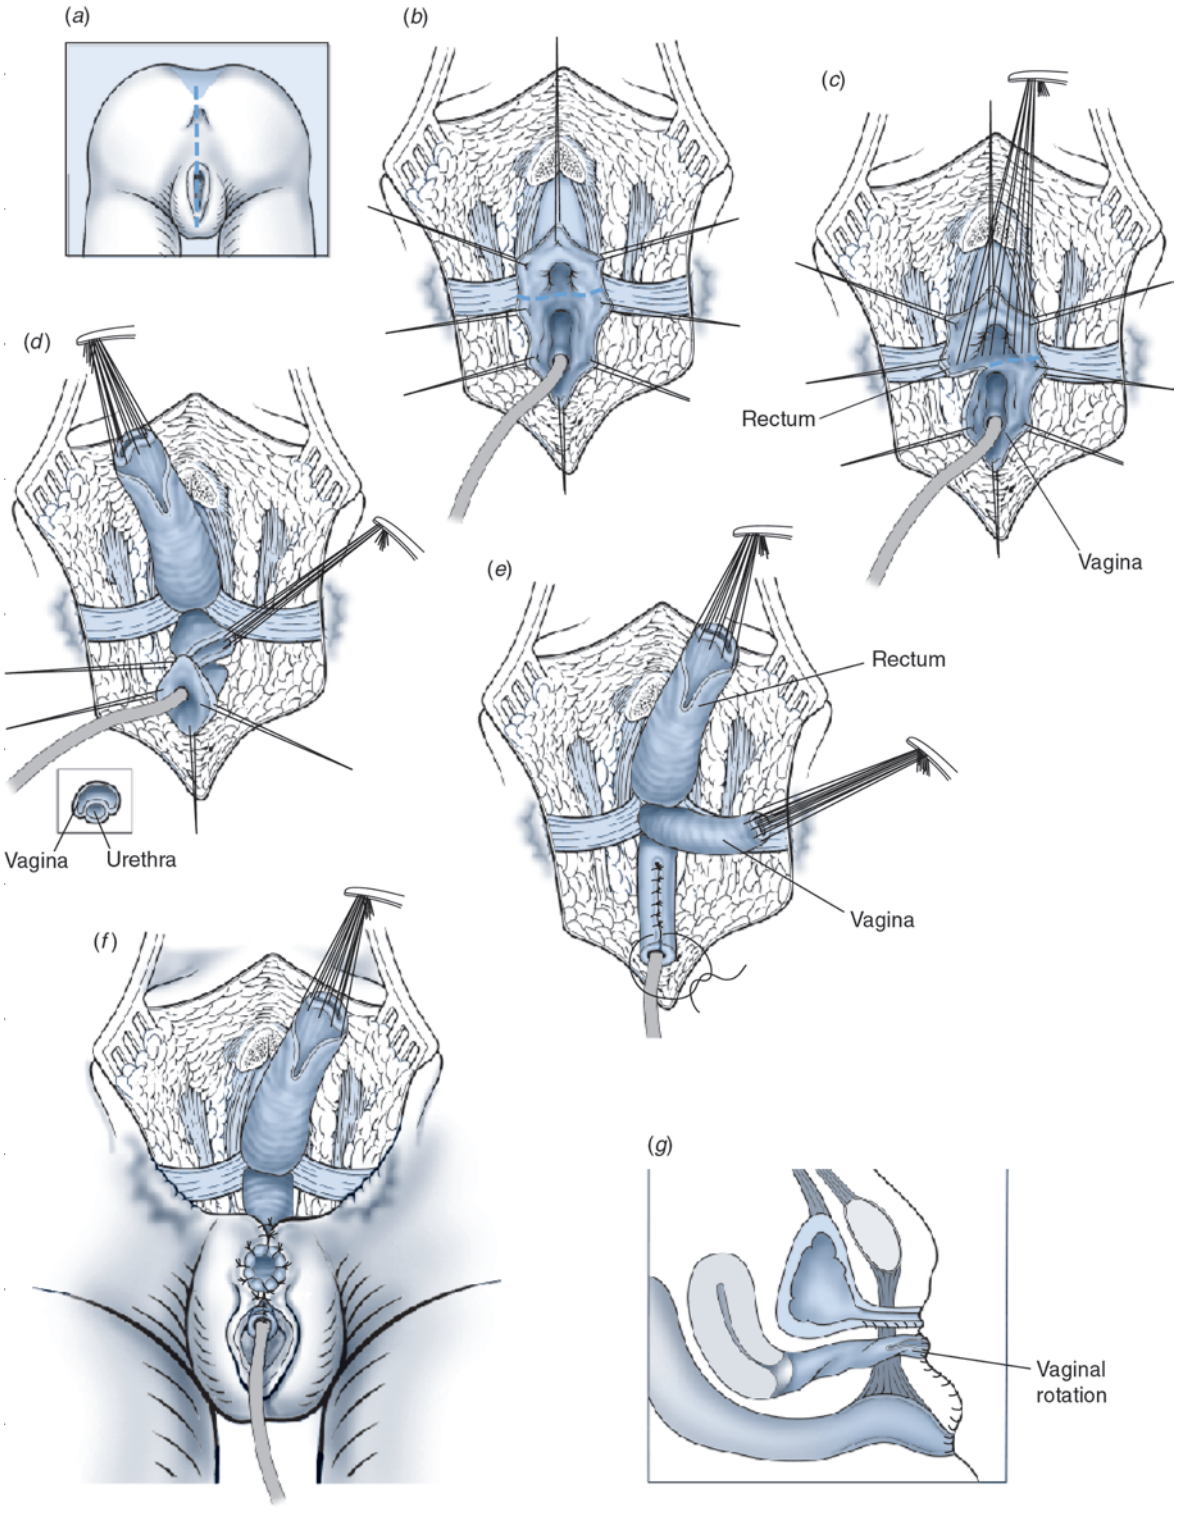

Figure 69.11 Cloacal reconstruction. See text. (Redrawn from Paidas and Peña.[45])

of these structures, which share a common wall, and because the vagina wraps itself around the dorsal half of the urethra (Figure 69.11c). Often, this dissection leaves a defect on the anterior surface of the vagina, which is sutured closed. The vagina is then mobilized and the urogenital sinus tubularized over a catheter to become the urethra (Figure 69.11d–e). A two-layer closure of skin separates the urethra and the vagina, which is then exteriorized (Figure 69.11f). When a vaginal suture line is present, the vagina is rotated 90°

to prevent overlapping suture lines and minimize the risk of urethrovaginal fistula (Figure 69.11g). The rectum and anus are reconstructed, as previously described for PSARP. These principles enable reconstruction of most complex anomalies with very successful outcomes. Figure 69.12a shows an infant following PSARUVP, and Figure 69.12b shows a second patient who received cloacal reconstruction. She has a neuropathic bladder managed by bladder neck reconstruction and intermittent catheterization, and a neuropathic rectum managed by continent cecostomy. She is continent of both urine and stool, and has normal vaginal depth and caliber for her age.

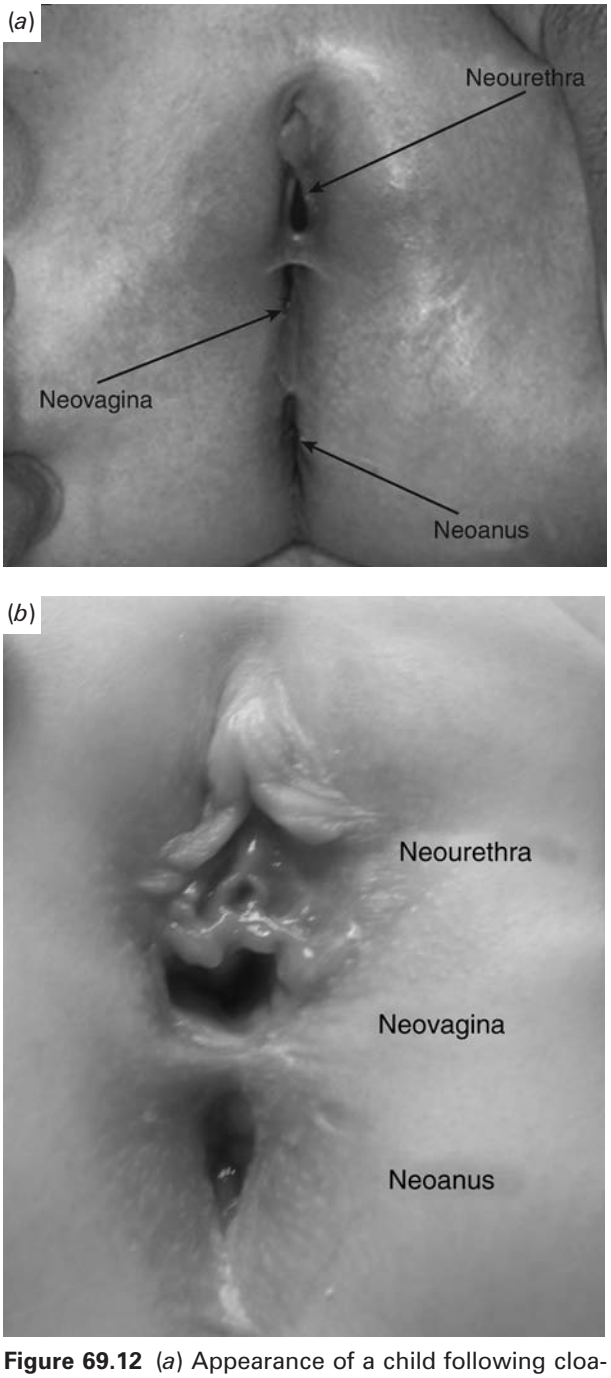

Figure 69.12 (*a*) Appearance of a child following cloacal reconstruction by posterior sagittal anorectal urethrovaginoplasty (PSARUVP). (*b*) Appearance of a second patient following = cloacal reconstruction.

Peña et al have reported long-term outcomes of cloacal reconstruction.[76] This large, single-center experience encompasses 339 patients over a 20-year period. They identified two distinct groups based on the length of the common channel. Patients with a common channel >3 cm have more complex malformations with more severe associated defects, which results in a lower likelihood of having the entire defect repaired by a posterior sagittal approach. They believe that total urogenital sinus mobilization is a reproducible maneuver for a successful repair in those with a common channel <3 cm.

Two groups have also reported long-term gynecologic problems following cloacal reconstruction.[76,77] A number of patients suffer from hematometra or hematocolpos at adolescence. It is important to detect atresias of the müllerian system early in life and reassess these patients at early puberty by imaging and perhaps vaginoscopy. Pena et al[76] have reported successful conception and delivery in two patients, both of whom had a short common channel cloaca.

Urologic reconstruction in patients with anorectal malformations

> Genitourinary reconstruction is best undertaken as an integral part of imperforate anus reconstruction. Failure to do so results in the loss of surgical alternatives, unnecessary reoperative procedures and compromised outcomes.[16]

The high incidence of urinary and genital tract anomalies in patients with imperforate anus, the morbidity associated with these anomalies, and the association of these anomalies with those accompanying ARMs mandates their integral management as part of the surgery for imperforate anus. Consequently, it is necessary that the general surgeon has a clear understanding of genitourinary pathology and that the pediatric urologist is familiar with the management of imperforate anus.

These patients are at risk for both urinary and fecal incontinence. It is inappropriate to treat urinary incontinence without solving the problem of fecal incontinence, because patients will still require diapers and

will not experience a significant change in their social integration. We address these problems concomitantly and in a coordinated fashion, as the treatment of one may have a significant influence on the management of the other. For example, anticholinergic therapy to control uninhibited detrusor contractions may adversely affect anorectal function by causing constipation. Similarly, loss of the ileocecal valve with procedures such as ileocecocystoplasty may exacerbate fecal soilage in patients with ARM by preventing the production of formed stool. Furthermore, sigmoid colocystoplasty in patients with imperforate anus runs the risk of ischemic injury to the anorectum by dividing the descending blood supply.

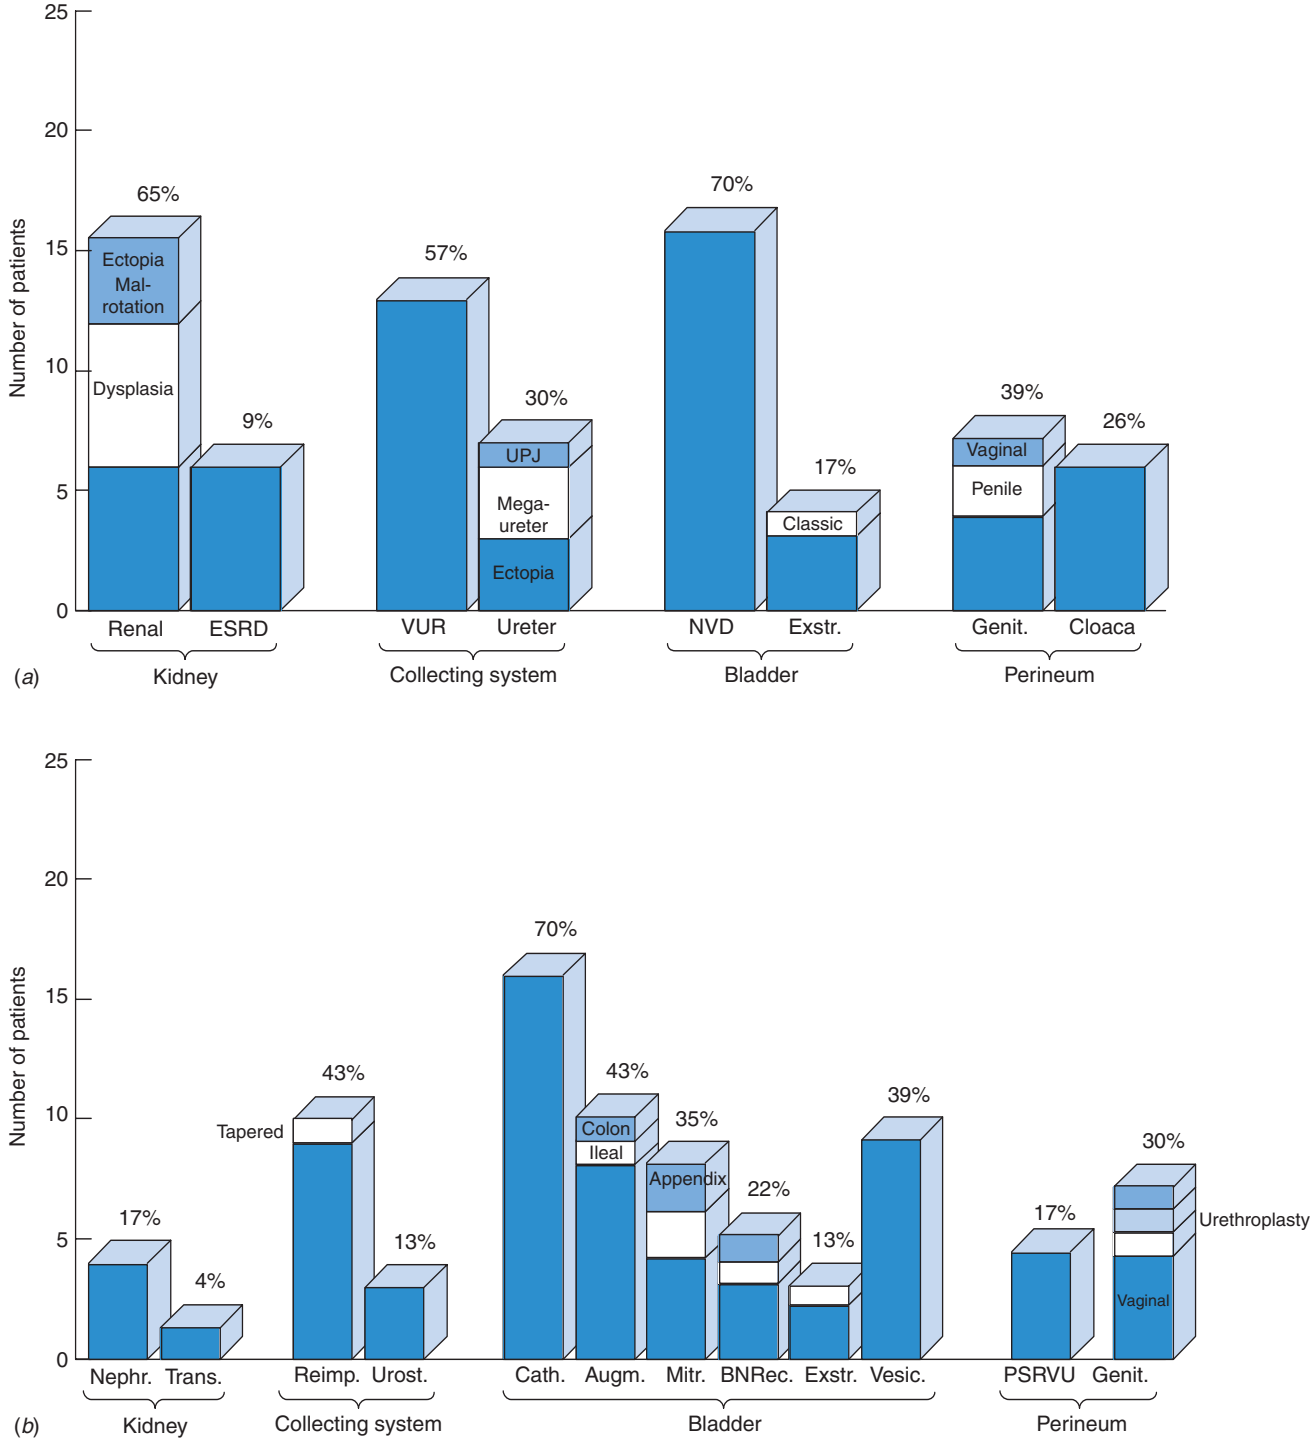

Figure 69.13 (*a*) Genitourinary abnormalities and (*b*) genitourinary surgical procedures in patients with anorectal malformations. NVD = neurovesical dysfunction. (From Sheldon et al.[16])

Incidental appendectomy must be avoided, because the appendix may be needed for either antegrade continence enema or Mitrofanoff neourethral bladder access. Imperforate anus surgery must be performed with an indwelling Foley catheter, because of the risk of inadvertent urethral injury. Inability to pass a catheter at the time of anorectal reconstruction is an indication for a cystoscopic evaluation and guidance in catheter placement. All patients with rectourinary fistulae, but especially those with VUR and/or neurovesical dysfunction, should have a fully diverting colostomy with a short distal colonic limb in order to prevent ongoing fecal urinary contamination. Placement of the colostomy is important. Patients at risk for future vesicostomy (e.g. high-grade VUR, neurovesical dysfunction, and hydrocolpos) should have the colostomy positioned so as not to interfere with a possible subsequent vesicostomy.

Sheldon has previously outlined the implications of genitourinary surgery in patients with ARMs.[16] Figure 69.13a reviews the genitourinary abnormalities encountered in 90 consecutive patients with ARMs managed over a 5-year period. Twenty-three patients had genitourinary anomalies requiring surgical intervention. Of these, 65% had primary renal pathology [9% had end-stage renal disease (ESRD)], 87% had collecting system abnormalities placing the kidneys at risk, 70% had neurovesical dysfunction, and 26% had CMs.

Figure 69.13b shows the genitourinary surgical procedures required for the reconstruction: note that 70% of children requiring urinary reconstruction ultimately required intermittent catheterization. The presence of a rectourethral fistula in the male may impair the ability to perform intermittent catheterization even after the fistula has been divided. Usually, intermittent catheterization can be performed with a coudé catheter. Diverticula, which may result in infection, voiding difficulties, and catheterization problems, may be managed by endoscopic fulguration.[78] Rarely, surgical excision may be required.

More than 40% of these patients required ureteral reimplantation and bladder augmentation. Twenty-two percent required bladder neck reconstruction for incontinence and 35% required a Mitrofanoff neourethra for alternate continent catheterizable bladder access. Nine patients required temporary vesicostomy, three for neonatal urosepsis, four for neurovesical dysfunction and hydronephrosis not responding to intermittent catheterization, one to control hyperchloremic metabolic acidosis, and one to relieve hydrocolpos complicating a CM.

Importantly, none of the 16 patients with neurovesical dysfunction had evidence to support PSARP as a source of bladder denervation. Further, four patients had urethral stricture. At least three of these were congenital. The fourth was suspected to be congenital but this was not proven by preoperative urethrography or endoscopy.

The 18 surgical complications occurring in 14 of these 23 children requiring genitourinary reconstruction are particularly instructive. Nine complications were secondary to surgery performed before referral to the author's institution. Four patients with a cloaca were referred for vaginal reconstruction after previous anorectal pull-through with no effort made to correct the UGSM. Two of these patients subsequently had urogenital sinus surgery using inlay flap techniques, and both of these developed urethrovaginal fistulae. Three patients had ureteral reimplantation before referral, which failed due to the associated neuropathic bladder.

Nine complications occurred following referral. Two children developed delayed small bowel obstruction that necessitated exploratory laparotomy and lysis of adhesions. One child experienced intraoperative vascular collapse from severe latex allergy. One patient developed a lymphocele following transplantation, and one patient developed a mild recurrent urethral stricture following urethroplasty for congenital stricture that urethral dilation addressed. One child developed a urethral calculus that occurred secondary to urethral erosion of a suture placed for approximation of the pubis for cloacal exstrophy reconstruction. Two children developed stenosis of their catheterizable channels corrected by stomal revision. Both had previously undergone incidental appendectomy such that one patient required a ureteral neourethra and the other a tubularized ileal neourethra. One patient reconstructed for a CM developed late vaginal stenosis.

This experience emphasizes several important principles:

1. Most neurovesical dysfunction and urethral strictures encountered in patients with ARMs are not iatrogenic but congenital in origin.
2. VUR is usually bilateral or, if unilateral, occurs in conjunction with a condition that threatens the contralateral kidney. In addition, neurovesical dysfunction often accompanies the VUR.
3. Ureteral reimplantation into a dysfunctional bladder usually fails unless the underlying bladder dysfunction is controlled.

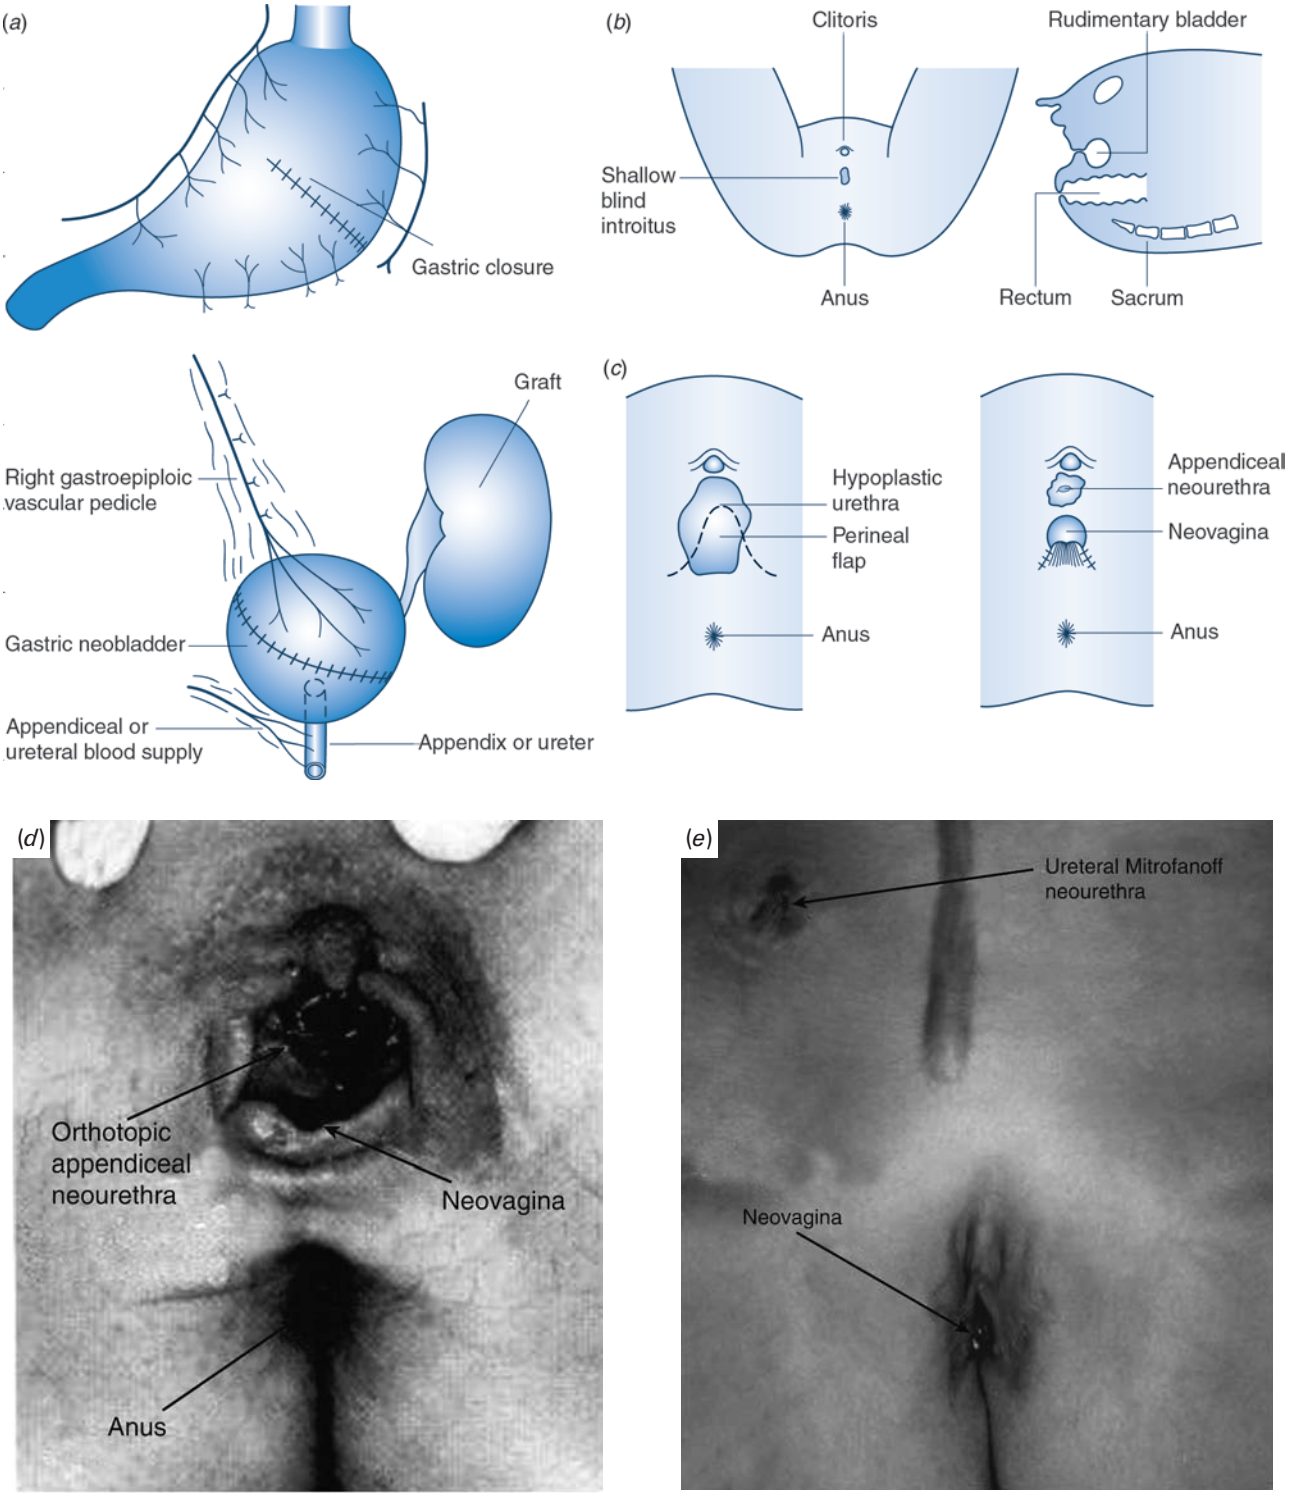

Figure 69.14 Vaginal reconstruction employing a bladder substitution technique: (*a*) total anatomic urinary replacement; (*b*) preoperative anatomy; (*c*) reconstruction employing a perineal inlay flap bladder substitution and an appendiceal neourethra. (From Sheldon et al.[84] and Sheldon and Welch.[85]) (*d*) Appearance of perineum of a child with a urogenital sinus malformation, a tiny hypoplastic bladder, and a rudimentary vaginal remnant employing an inlay flap bladder substitution technique. (From Sheldon et al.[84]) (*e*) Appearance of a child with a urogenital sinus malformation, a tiny hypoplastic bladder, and a rudimentary vaginal remnant reconstructed employing an inlay flap bladder substitution technique. A composite neobladder (stomach and ileum) was constructed along with a ureteral Mitrofanoff neourethra.

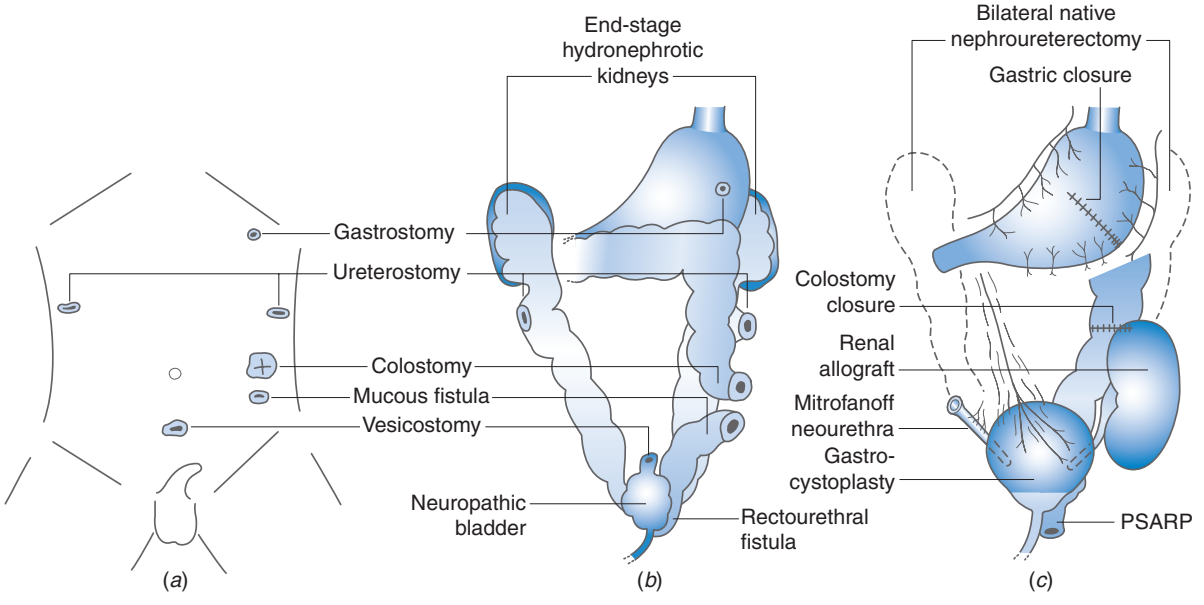

Figure 69.15 Urinary reconstruction and renal transplantation in a patient with the VATER association: (*a*) preoperative appearance; (*b*) preoperative urinary and colonic status; (*c*) postreconstructive status.

4 Prompt and efficient decompression of obstructive hydronephrosis is essential in order to optimize long-term renal function.
5 Patients with ARM have a similar risk for latex allergy as do the myelomeningocele population.
6 The combination of neurovesical dysfunction or urethral stricture and rectourinary fistulae predisposes the patient to critical neonatal illness such as sepsis and hyperchloremic metabolic acidosis.
7 A low, fully diverting colostomy is most protective of the urinary tract.
8 Patients with a cloaca should never have their anorectal and UGSMs corrected separately.

The best results are attained using a single-stage PSARUVP. Those patients who present for correction of a UGSM who have previously undergone an anorectal pull-through procedure are best corrected by reoperative PSARUVP complete with repeat mobilization of the rectum. Both patients managed in this fashion in this series were successfully reconstructed.

Renal transplantation in patients with anorectal malformations

Renal transplantation in the setting of ARMs and CM deserves additional comment. ESRD in this setting may considerably complicate management.[79–81] Peritoneal dialysis is more difficult, or may be impossible in the presence of multiple adhesions from prior transabdominal surgical procedures. Surgeons should make every effort to preserve the peritoneal cavity in the very young, because hemodialysis access is difficult and is associated with long-term complications such as superior vena cava thrombosis.

Renal transplantation in patients with ARMs and UGSMs is extremely challenging, as the majority of these patients with ESRD have major bladder pathology that must be controlled or corrected before transplantation, in order to optimize outcome. In addition, vascular anomalies are relatively common in these children.[82] Successful renal transplantation, however, in the setting of imperforate anus and cloacal anomalies, can be achieved.[79–81,83]

The complex nature of transplant management in these patients is illustrated by the following three cases. The patient in Figure 69.14 presented with a cloacal anomaly with a tiny hypoplastic bladder, a rudimentary vagina, and ectopic ureters draining dysplastic kidneys. She underwent creation of a neovagina using the hypoplastic bladder and then underwent total anatomic urinary replacement with the creation of an appendiceal orthotopic neourethra and an orthotopic gastric neobladder, followed by living related donor transplantation.

The second child was born with cloacal exstrophy and had the cloacal plate removed as an infant. She was managed with an ileostomy and a cutaneous ureterostomy draining a solitary kidney. This kidney was lost over the ensuing years from hydronephrosis and urosepsis. She presented for renal transplantation

and underwent creation of an orthotopic neourethra using a segment of ureter and creation of an orthotopic neobladder using a gastric segment. She subsequently underwent renal transplantation. Both of these patients with total anatomic urinary tract replacement continue to have satisfactory renal function and are continent of urine on intermittent catheterization.[85]

The third patient (Figure 69.15) presented after several decompressive procedures at the referring institution. These included a gastrostomy, a colostomy with mucous fistula for imperforate anus, a vesicostomy for neuropathic bladder, and bilateral cutaneous ureterostomies for bilateral hydronephrosis accompanied by profound renal insufficiency. This child presented with ESRD for transplantation. His surgical preparation consisted of posterior sagittal anorectoplasty, followed by takedown of colostomy, gastrocystoplasty, creation of a Mitrofanoff neourethra, and native nephrectomy. He subsequently underwent living related transplantation. He now has excellent renal function and is continent of urine on intermittent catheterization.

Conclusion

The principles outlined in this chapter regarding the management of ARMs and CMs, along with the advancements in the science of perioperative surgical management and transplantation, have enabled even those children born with the most devastating congenital anomalies to be restored to health and a functional social status.

Surgery for intersex disorders and urogenital sinus

70

Mark C Adams and Romano T DeMarco

Introduction

Advances in surgical management have improved both the cosmetic and functional outcomes of patients with urogenital sinus abnormalities and those with varying degrees of intersexuality, at least, when judged by treating surgeons. Descriptions in early textbooks of methods such as clitoridectomy or convenient 'forgetting' of the hypoplastic vagina are now considered archaic because of improved understanding of genital anatomy and function. Better exposure and innovative techniques have produced surgical improvements hardly thought possible half a century ago. While our understanding of these complex problems is better, it is not complete. Much remains to be learned about female genital function, the affects of surgery on genital innervation, and the significant psychological affects of these problems and their reconstruction on the patient.

Genital development and implications for surgery

Normal development in any organ system proceeds through a highly regulated and complex cascade of interactions. Errors in development virtually always occur in a spectrum of severity and can lead to minor, inconsequential aberrancies or profound problems affecting patient survival. Similarly, embryologic errors in the urogenital tract have a wide range of magnitude. Genitourinary embryology is discussed in detail in Chapter 67.

Under the influence of SRY (the sex-determining region of the Y chromosome) the bipotential gonad should differentiate into a testis near the 7th week of gestation. Normal phenotypic expression of male differentiation is then actively controlled by secretion of MIS (müllerian inhibiting substance) by Sertoli cells and testosterone by Leydig cells. MIS causes rapid regression of the paramesonephric (müllerian) ducts between the 8th and 10th weeks. In normal females, the absence of the Y chromosome and SRY protein secretion leads to the formation of ovaries without Sertoli or Leydig cells. The absence of such cell types prevents elaboration of MIS and androgens. Subsequently, the paramesonephric ducts give rise to the fallopian tubes, uterus, and the upper two-thirds of the vagina. The distal third of the vagina is formed from endodermal tissue, the sinovaginal bulb. In simple terms, the female phenotype has been thought of as the passive or default sex, forming in the absence of the Y chromosome. Exceptions to this cascade do exist.[1]

In a sense, normal males have a persistent urogenital sinus with ultimate entry of the wolffian ducts as well as a remnant of the müllerian system at the verumontanum. It would seem, therefore, that the most proximal confluence of a persistent urogenital sinus in a female would be the area of the proximal urethra. Whereas the vast majority of girls with a urogenital sinus anomaly have a confluence at that level or more distally, exceptions do occur. The vagina may be found entering the bladder itself even cephalad to the level of the ureteral orifices. It is not known whether the müllerian duct opening may migrate into the bladder in tandem with the ureteral bud or whether there is simply an abnormal breakdown in communication between these intimate structures.

The normal vagina has two embryologic components. The complex development may contribute to the typical appearance of the vagina in the setting of a urogenital sinus. The distal portion of the vagina is virtually always narrow for a variable length (Figure 70.1). Recognition of that finding is critical in surgical reconstruction. Failure of flaps to reach all the way through the narrow segment and well into the more normal proximal portion may ultimately lead to stenosis. The paramesonephric ducts and entire müllerian

system are initially paired structures which should fuse distally in the midline. Errors in fusion do occur,[2] and patients with a persistent urogenital sinus or cloaca may be at increased risk for such problems (Figure 70.2). In the setting of a urogenital sinus, the finding of a vagina to either side of the midline should arouse suspicion that a second vagina, even if obscure or obstructed, may well exist on the other side. Failure to recognize the second vagina at the time of reconstruction may eventually lead to hydrometrocolpos.

Classification scheme

A urogenital sinus abnormality is present when a persistent communication occurs between the genital and urinary tract in the female. Typically, the urethra and vagina are joined and exit to the perineum as a common channel. If there is associated rectal involvement and imperforate anus with a single perineal opening for all three structures, a persistent cloaca or cloacal anomaly exists. A urogenital sinus with an anteriorly displaced rectum may represent the form früste of a persistent cloaca. Such a finding may have implications for rectal function and exposure during surgical reconstruction of the urogenital sinus. Patients with urogenital sinus anomalies commonly have associated abnormalities of the clitoris, labia, and external genitalia. The most common etiology of a persistent urogenital sinus is congenital adrenal hyperplasia (CAH).

The most useful classification schemes for urogenital sinus anomalies relate to the level of the confluence of the urethra and vagina. Hendren made a landmark contribution to genital reconstructive surgery when he divided urogenital anomalies into those with a confluence above or below the female external sphincter and suggested that a different surgical approach was indicated for the two types.[3] In females with extreme virilization related to CAH, the external sphincter may be well developed and quite obvious. In most females, the sphincter mechanism may be indistinct and the level of the pelvic floor a more reliable landmark. The absence of a well-defined external sphincter in such patients has led to subjective classification based on the level of confluence as low, moderate, or high. It is important to recognize that the level of the confluence should be considered relative to the bladder neck and not the external meatus. Virilization of the distal urethra or urogenital sinus may create a confluence that is distant from the meatus yet still relatively low. The critical determinant, therefore, is the distance from the bladder neck to the confluence as it affects reconstructive surgery (Figure 70.3). Rink et al[4] have proposed a more rigid classification scheme based on careful measurements from both directions.

The nature of the urogenital sinus distal to the confluence should also be considered. Hendren described

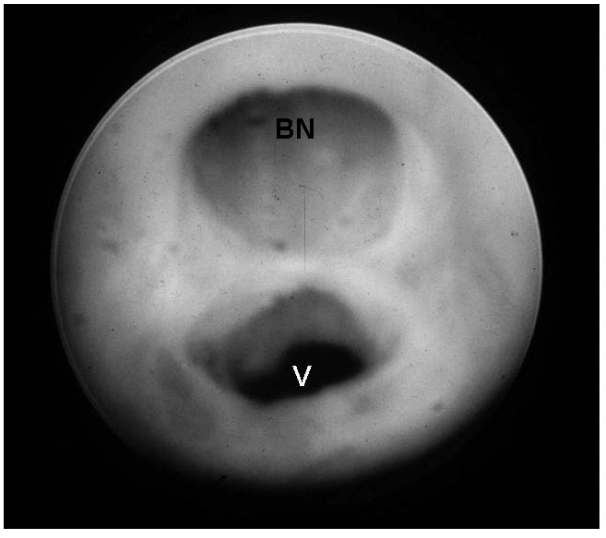

Figure 70.3 Endoscopy. A vaginal opening (V) this close to the bladder neck (BN) represents a high confluence no matter the distance from the external meatus.

the urogenital sinus distal to the confluence as urethra-like or vagina-like based on circumference.[5] This difference has typically been applied in descriptions of a persistent cloaca but may be useful for isolated urogenital sinus anomalies as well. The difference between the two has potential ramifications on surgical reconstruction in terms of the amount of local tissue available for reconstruction of the urethra or vagina.

Evaluation

A thorough evaluation of the newborn with a urogenital sinus should be completed expeditiously. Immediate attention to and stabilization of any fluid or electrolyte imbalance is paramount. Delays in appropriate medical evaluation of those patients with CAH and unrecognized salt wasting carry significant risks. Initial screening studies in such patients include assessment of serum electrolytes, biochemical assays screening for CAH, and evaluation of karyotype using cultured peripheral leukocytes. A multidisciplinary assessment is initiated, including medical professionals from neonatology, endocrinology, child psychiatry, medical genetics, urology, and at times medical ethics. Gender assignment based on karyotype and potential for genitourinary function should be made after discussion within the entire treatment team and the parents. A child should not be named until the appropriate gender assignment is made.

History/physical examination

A careful maternal and family history is mandatory. Maternal use of alcohol or drugs and exposure to androgenic substances as well as a family history of previous neonatal death, infertility, genital ambiguity, abnormal pubertal development or inguinal hernias associated with retained müllerian structures may contribute to proper diagnosis.

Physical examination of the child is important and may provide further clues. The general well being of the child should be assessed. Signs of dehydration and lethargy suggest a diagnosis of CAH. Patients with 11 β-hydroxylase deficiency may be hypertensive. The abdominal examination should note any lower, midline abdominal masses which might represent a distended bladder or vagina. The back should be assessed for any findings associated with an underlying neurologic anomaly. Gonads are palpated to determine location, number, size, and associated structures such as an epididymis and vas deferens. Rectal examination should carefully evaluate the location of the anus, and palpation with the little finger may identify the midline cervical cap or uterine tissue. Careful inspection of the female introitus is required to identify an isolated urogenital sinus if no clitoral or labial abnormalities are present.

Radiographic evaluation

Ultrasound is a valuable adjunct to physical examination in these patients. The newborn period is the optimal time for evaluation because maternal hormones make the ovaries and uterus more prominent.[6] The spinal cord may also be evaluated for cord tethering. Although sometimes helpful, the sensitivity for locating a non-palpable or intra-abdominal gonad with sonography is at best 60%.[7] Hydrocolpos, in this setting usually related to retained urine, and bladder distention are easily seen with sonography. Likewise, the kidneys should be evaluated for hydronephrosis, dysplasia, and agenesis. Additionally, patients with CAH usually have a cerebriform appearance of their adrenal glands that may be helpful in diagnosis.[8]

All patients with a urogenital sinus anomaly should undergo contrast genitography. These studies require interest, skill, and determination on the part of the radiologist. The study may be performed by insertion of the tip of a Foley catheter into the opening of the urogenital sinus. The balloon may then be inflated outside the meatus to prevent spillage of contrast, and retrograde instillation of radiopaque dye used to define the anatomy. In many cases it is then possible to

advance a feeding tube into the bladder for formal voiding cystourethrography. Proper studies should define the length of the common sinus and the level of confluence. Pelvic magnetic resonance imaging (MRI) may, at times, add anatomic detail or understanding.

Endoscopic evaluation

Endoscopic evaluation of the anatomy is critical and should be performed on all children with a urogenital sinus. Generally, this is done under the same anesthetic as open reconstruction, particularly for lower or intermediate lesions. If the anatomy is not well understood after radiographic evaluation, particularly in the presence of a high confluence or after failure to identify any vaginal structure on genitography, cystoscopy may be performed alone in order to better understand or delineate the anatomy and better prepare the patient and family for reconstructive surgery.

Further studies

In rare circumstances usually related to the diagnosis of intersex, the definite diagnosis may remain elusive after conventional studies. At times, relatively prolonged hormonal stimulation to evaluate the presence and function of testicular tissue may be indicated. Gonadal biopsy may be necessary for diagnosis. An adequate biopsy requires a full length, deep longitudinal incision into the gonad to ensure adequate tissue sampling. This may be done in an open fashion or laparoscopically. Such a procedure allows for thorough examination of the pelvis and abdomen for müllerian and wolffian structures.

Surgical techniques

Timing

Significant improvements in surgical techniques and outcomes have occurred over the past several decades. Despite these apparent improvements, controversies remain. Intersex advocacy groups, patients, and some medical professionals still question the timing of surgery and whether reconstruction should be performed at all until the patient can contribute to informed consent. Discussions with a multidisciplinary team and parents must address these controversies prior to female genital surgery. Today, most genital reconstructive surgery is performed with respect to genetic sex. Only in very rare situations is gender conversion considered.

Most girls with a urogenital sinus diagnosed as infants have CAH. It is generally accepted that clitoroplasty for those patients is best performed in the first few months of life. Waiting several months allows good stabilization of the patient from an endocrine and metabolic standpoint. Appropriate medical treatment will, at times, produce improvement in the external virilization, but seldom results in complete normalization. Relatively early intervention may carry the benefit of thicker, more vascular skin and easier dissection or manipulation of the clitoris and paravaginal tissue related to maternal estrogen stimulation. There may also be some psychological benefit for the parents from early correction of the virilized external genitalia.

In contrast to timing of clitoral reduction, the optimal age for vaginal reconstruction is more controversial. It is our belief that total genital reconstruction with vaginoplasty should be performed as a single stage with clitoroplasty within the first several months to first year of life. This is particularly true for patients with CAH, most of whom have clitoromegaly and a low to moderate confluence of the urogenital sinus. Potential benefits include improved tissue transfer and reduced scarring secondary to estrogen stimulation, minimization of parental anxiety over the child's condition, and earlier self-acceptance of the child's gender identity and genital anatomy. It must be noted that delayed vaginal construction is recommended by some surgeons.[9] Early vaginal reconstruction may carry an increased risk for an element of vaginal stenosis when evaluated in the adolescent or young adult.[10] Advocates for delayed reconstruction note psychological concerns in older patients with subsequent vaginal stenosis particularly when vaginal dilatation is required. It is not clear that the psychological impact of later, major reconstruction for vaginoplasty will carry a lesser psychological impact on the patient. We favor complete, early repair as we have found the exposure and surgical reconstruction then to be considerably easier than in an older patient and value the increased availability of genital skin from the clitoris for vaginal reconstruction.

Patient preparation

Most children undergoing vaginoplasty for a urogenital sinus anomaly, unless the confluence is extremely low, undergo a full bowel preparation using a polyethylene glycol and electrolyte solution such as GoLYTELY. For young children, this preparation is done as an inpatient with bowel catharsis adminis-

tered by a nasogastric tube. Adolescent patients may self-administer the bowel preparation orally at home with parental guidance. A series of oral antibiotic doses are often administered as well as perioperative broad-spectrum intravenous antibiotics.

After general anesthesia is administered, the child is usually placed in the dorsal lithotomy position for endoscopy. Even if endoscopy has previously been performed in the newborn period, we generally repeat endoscopy at the time of surgical reconstruction, as the internal genital findings may be much more obvious in an older patient. The rectum and distal colon may be irrigated clear of any residual fecal matter at this time. For higher lesions, a Foley catheter is placed into the bladder, and a second catheter, either a Fogarty or Foley, is placed into the vagina. Cystoscopy aids in confirmation of catheter placement in the appropriate position.

Surgical preparation is dependent on the extent of the planned reconstruction and surgeon preference, as well as on the age of the patient. In all but the lowest of urogenital lesions, we perform a full, lower body prep from the nipple to toes, front and back (Figure 70.4). The catheters are kept sterile and prepped into the surgical field. The feet and lower legs are wrapped, and the patient passed through an aperture in the surgical drape. This preparation allows exposure to the entire lower body in both the prone and supine position. It is simple and safe to move smaller patients between the two positions. It is often helpful to perform the external feminizing genitoplasty with the patient supine, while exposing and repairing the proximal sinus in the prone position. Trying to prep and move a larger teenage patient in a similar fashion may be cumbersome and impractical. If prone positioning is desired for exposure and vaginoplasty in such patients, a modified skydiver position may be used. Positioning and padding must be utilized carefully to avoid injury.

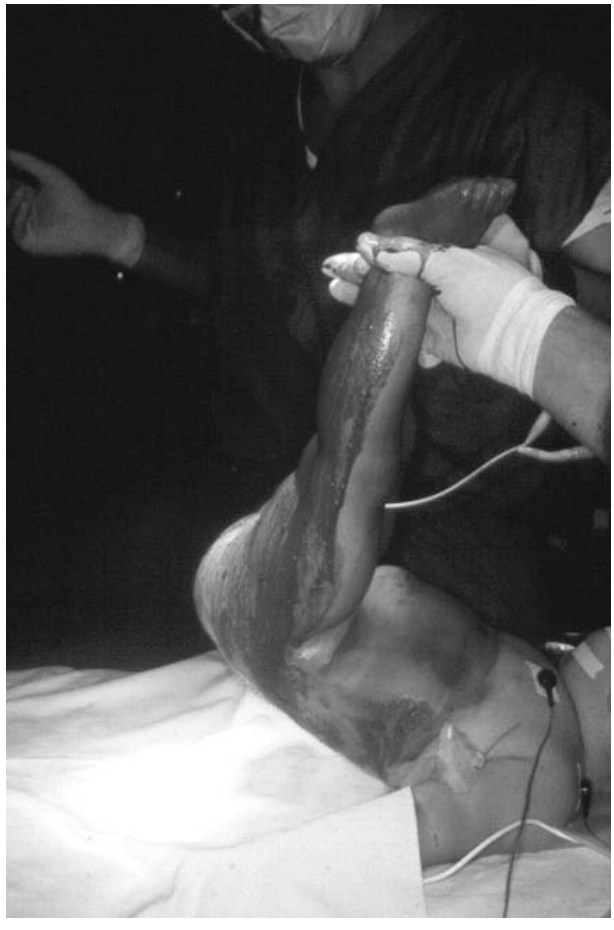

Figure 70.4 Lower body preparation. The preparation allows supine and prone approach. Smaller patients may be easily turned between the two positions.

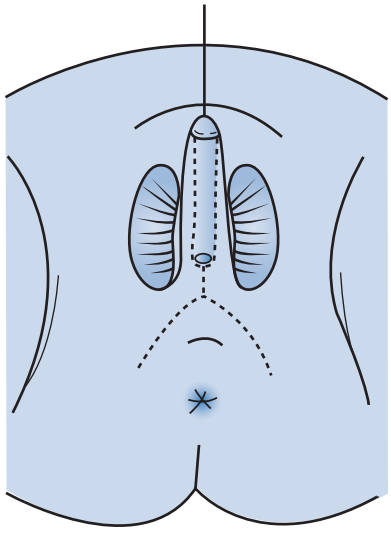
Feminizing genitoplasty

The surgical management of the child with clitoromegaly has undergone marked evolution from early methods that advocated clitoral amputation.[11,12] Although satisfactory cosmetic results were reported after such procedures,[13] impairment in orgasm and psychosexual development were later noted.[14] The first attempts at sparing the clitoris with modification of the appearance involved clitoral recession or concealment.[15–17] All current techniques have preservation of clitoral sensation and function as their cornerstone. Those repairs are based on Schmid's landmark description of corporeal body excision and neurovascular bundle conservation.[18] Early reports described complete excision of the corpora cavernosa of the phallus, including the tunica, while the neurovascular bundle was preserved only with Buck's fascia.[19] It then became clear that subtunical resection of the corporeal erectile tissue with preservation of the dorsal tunica might protect the glanular nerve and blood supply.[20] Recently Baskin and colleagues have suggested that a more ventral tunical incision may be prudent after carefully demonstrating lateral fanning of the clitoral nerve supply.[21] Other interesting work has helped to define the spatial relationship of the normal clitoris, urethral meatus, vaginal introitus, and other anatomic landmarks,[22] as well as begun to examine which areas of external genital skin may be most involved in genital sensation and orgasm.[23]

Clitoral resection is performed with the child supine with legs spread or in a low lithotomy position. A traction suture is placed in the glans clitoris,



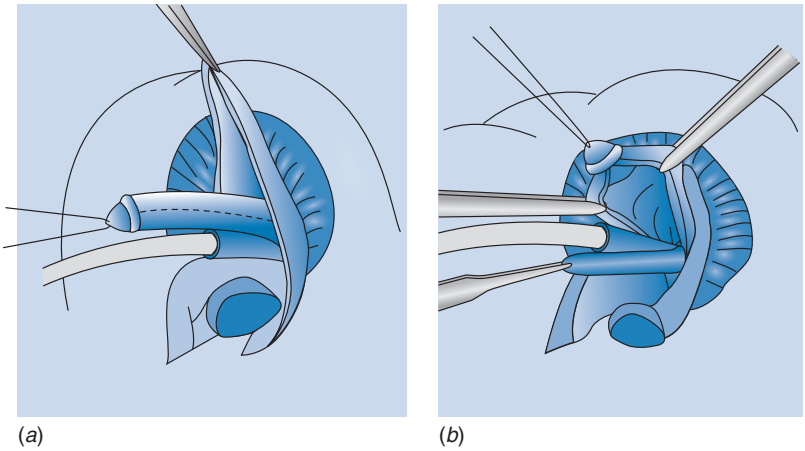


Figure 70.5 Feminizing genitoplasty. The dashed lines mark the initial incisions. (From Rink RC, Adams MC,[26] with permission from Springer Science and Business Media.)

(*a*) (*b*)

Figure 70.6 Corporeal reduction. (*a*) The urethral plate and spongiosum are mobilized off the ventral corpora. The dashed line shows the ventromedial incision into tunica on either side. (*b*) The erectile tissue is excised with ventral tunica. (Adopted from Rink RC, Kaefer M,[102] with permission from Elsevier.)

and the initial incision is marked and made in a circumcising fashion just off the glans over the dorsum and lateral aspect of the clitoris. Ventrally, the incisions are carried in a parallel fashion from distal to proximal on either side of what would be the urethral plate (Figure 70.5). These incisions are carried proximally to the urethral meatus. The lines of incision and base of the clitoris may be infiltrated with 1:200 000 epinephrine with or without lidocaine for aid in hemostasis. Incisions are carried down to Buck's fascia and the clitoris degloved of phallic skin. The urethra is generally left attached to the glans with consideration of glanular blood supply while the urethral plate with spongiosum is dissected off of the corpora cavernosa to expose the ventral tunica of the cavernosa.

The tunica of the corpora are incised proximally at their bifurcation on the ventromedial side (Figure 70.6). Longitudinal incisions are carried out towards the glans all the way through the tunica to expose the erectile tissue. Erectile tissue is sharply excised from the proximal bifurcation out to the level of the corona along with the ventral tunics. The proximal ends of erectile tissue may be oversewn or suture ligated for hemostasis. Even after treatment with steroids, the glans clitoris may be remarkably enlarged. If so, the

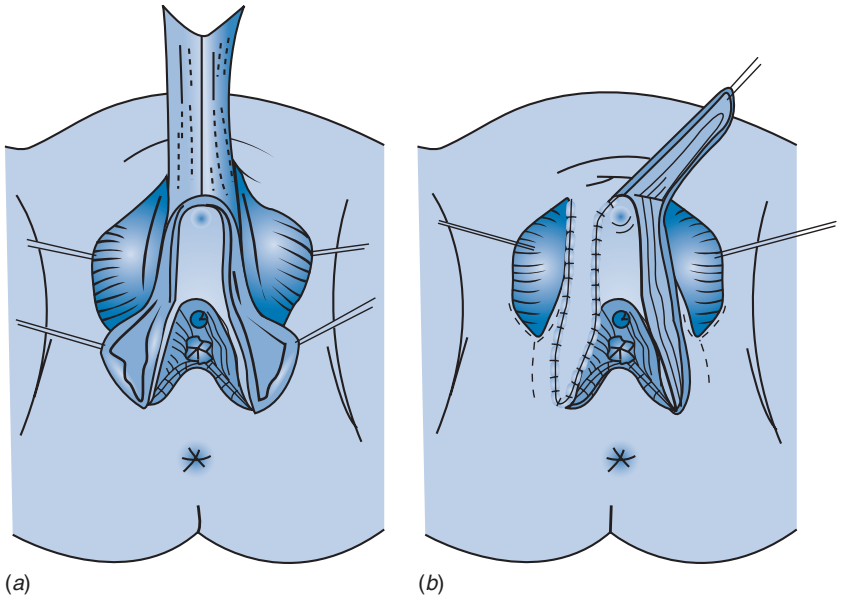

Figure 70.7 Labioplasty. (*a*) Redundant dorsal phallic skin is mobilized and incised in midline. (*b*) The phallic skin is used as labia minora on either side. Y-V plasty is performed on the labia majora. The posterior flap is advanced into the vagina. (Adapted from Rink RC, Adams MC,[26] with permission from Springer Science and Business Media).

glans may be reduced by excising a wedge of glanular tissue on the ventral surface. Baskin et al have shown that ventral excision of the glans is the most appropriate when considering the nerve supply.[21] The reduced glans should be approximated to the base of the corporeal bodies by anchoring sutures. The location of the glans should give consideration to the position of the clitoral hood and symphysis pubis.

Feminizing genitoplasty also involves construction of labia minora from clitoral skin as well as modification of the labia majora (Figure 70.7). The phallic skin is released dorsally and unfurled by mobilizing the inner from outer prepuce. The skin is then usually incised in the dorsal midline. The midline incision is stopped short of the base of the phallus in order to preserve an appropriate hood over the dorsal clitoris. The excess skin is rotated ventrally, trimmed, and approximated to either side of the urethral plate medially as well as the modified labia majora laterally. The flaps, as such, serve as labia minora. Alternatively, the phallic skin may be used for an anterior vaginal flap in more proximal repairs. The labia majora, as the result of virilization, are initially short and rounded. Aggressive incision around the medial, posterior, and lateral aspect of the labia majora on either side allows the labia to be lengthened and narrowed using a Y-V plasty. This plastic reconstruction of the labia is often performed in conjunction with flap vaginoplasty, and modifications in the posteriorly based vaginal flap may allow the labia from either side to swing inwards posteriorly and avoid an overly wide posterior introitus.[24]

Surgical correction of the low confluence

Cutback vaginoplasty

A cutback vaginoplasty is a simple procedure performed in the patient with labial fusion. This technique involves incision of the fused skin posteriorly to the perineum to expose the vaginal orifice. The incised lateral edges are oversewn. Whereas such a procedure is simple and may produce a good result in the appropriate patient, it is only a consideration in patients with a common urogenital sinus on the phallus with confluence of a normal vaginal opening at the level of the perineum. That combination is extraordinarily rare; thus the procedure is very rarely, if ever, indicated.

Flap vaginoplasty

Flap vaginoplasty is best suited for those patients with a low confluence of the urogenital sinus. The perineal skin incision is marked and made as a broad-based, inverted U-flap.[25] The closed end of the flap is created at the posterior lip of the meatus of the urogenital sinus, and the lateral margins should be well inside the ischial rami. The flap may be variable in length, depending on the length of the urogenital sinus; however, the posterior extent should leave a normal-sized

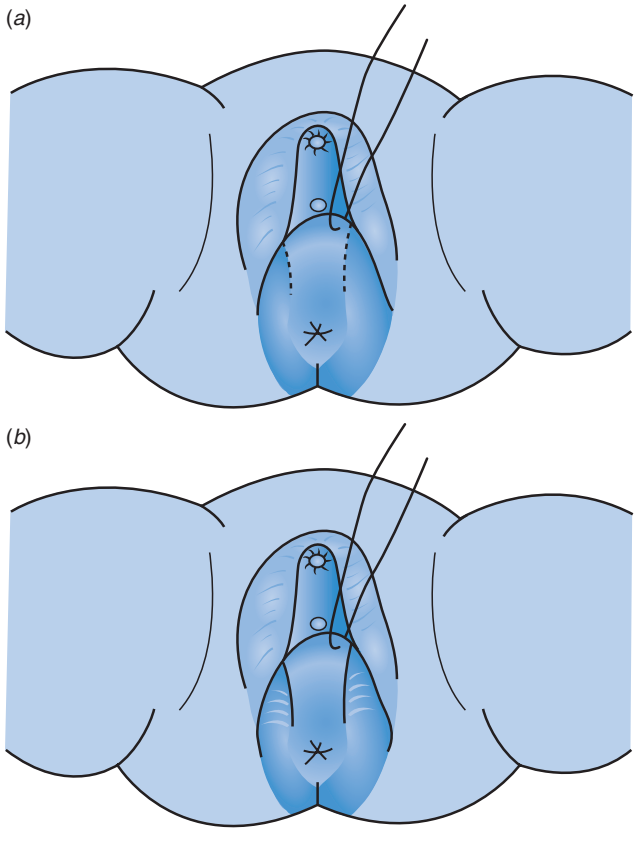

Figure 70.8 Omega flap. Skin elements may be excised carefully at the base of the flap to create a more normal-appearing posterior introitus. Subcutaneous tissue and blood supply should be preserved at the base.

perineal body. Design of the flap should respect considerations of the length versus width so as to ensure a good blood supply. Maintaining a U shape rather than narrow V shape at the tip anteriorly helps to make sure that the end of the flap is not ischemic.[26] The skin flap should be mobilized away from the posterior aspect of the urogenital sinus while maintaining a thick layer of subcutaneous tissue and fat with the flap. This mobilization exposes the urogenital sinus, which is eventually incised in the midline posteriorly. The incision is carried into the vagina and must extend through the distal vagina, which is typically narrow. Failure to place the flap well into the proximal vagina that is normal in circumference may result in stenosis. The flap of perineal skin is advanced into the vagina and secured with interrupted absorbable suture and should reach without tension (see Figure 70.7).

The broad-based flap may create an abnormal appearance to the introitus posteriorly when the labia are spread. Careful trimming of the dermis and epidermis at the base of the flap may allow creation of a rhomboid or omega shape without sacrificing viability of the flap[24] (Figure 70.8). Posterior excision of the skin should not be so extreme as to compromise the vascularity of the flap, and the subcutaneous tissue must be carefully preserved at that level. Modification of the flap allows subsequent use of the labia to provide some posterior closure of the introitus and a more normal appearance.

It should be noted that flap vaginoplasty does not totally correct the urogenital sinus. Without any separation of the vagina from urethra and lengthening or advancement of the urethra itself, the patient is still left with a urogenital sinus. The sinus, however, is much broader distally and may, therefore, not be of any functional or cosmetic significance. Consequently, flap vaginoplasty should not be a viable surgical option for correction of a high-confluence urogenital sinus. One appropriate role for total urogenital mobilization may be to advance the level of confluence towards the perineum in a patient with a moderate-level lesion in order to make conventional flap vaginoplasty an appropriate technique for repair.

Surgical correction of the higher confluence

Pull-through vaginoplasty

This repair, as described by Hendren and Crawford,[3] was a landmark advance in female genital reconstruc-

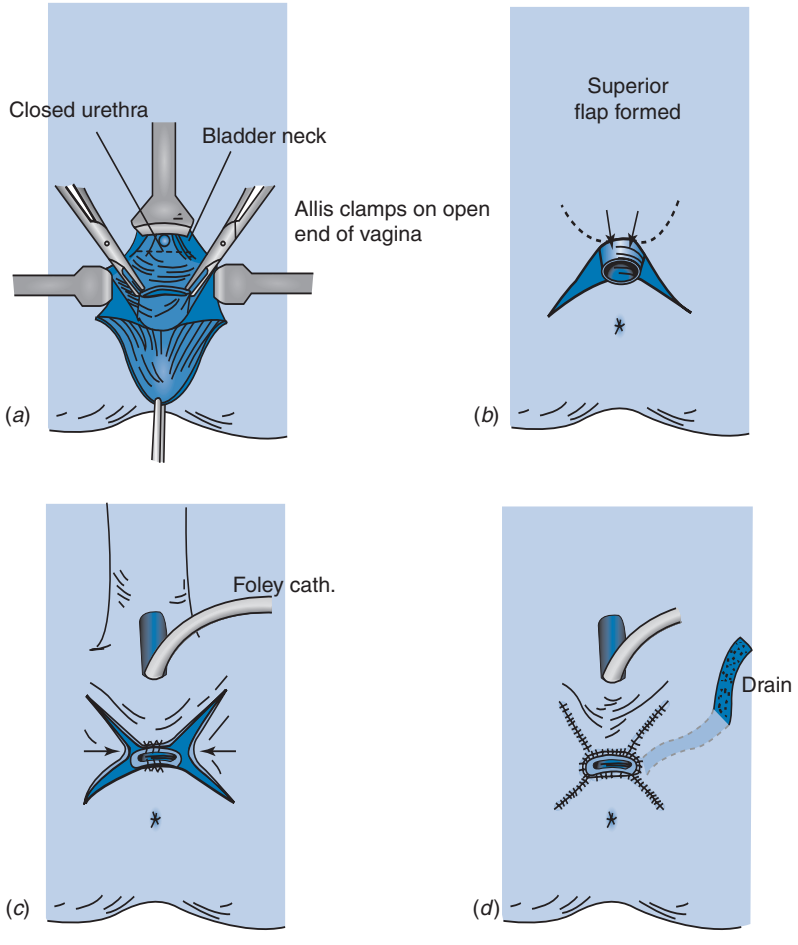

Figure 70.9 Pull-through vaginoplasty. The vagina is mobilized off of the urogenital sinus and advanced to the perineum. The sinus is closed to creat the urethra. (Adapted from Hendren WH, Crawford JD,[3] with permission from Elsevier.)

tive surgery; its basic principles still apply for children with higher lesions. Hendren's initial description includes the use of shallow, opposing U-shaped incisions on the perineum at the spot for placement of the eventual vaginal introitus[3,25] (Figure 70.9). Dissection is then made parallel and slightly posterior to the distal urogenital sinus until the vaginal catheter is encountered. A finger placed in the rectum may help maintain the proper plane of dissection posteriorly. The vagina is divided at its entrance to the sinus and then mobilized extensively. The proximal urogenital sinus at the site of prior confluence is closed, and the urogenital sinus used as a functional urethra. As originally described, the vagina is mobilized extensively in a circumferential fashion. The proper plane of dissection between the proximal urethra and anterior vagina is always quite difficult. For the first several millimeters, there is often virtually no connective tissue between the mucosa of the two structures. Dissection must continue through this difficult area in order to achieve adequate mobilization, and Hendren[3] and others[27] initially promoted mobilization of the vagina to the extent that it could be advanced as is to the perineum. Avoidance of the bladder and urethral sphincter mechanisms is mandatary as one proceeds proximally. In general, it is better to err by dissecting too close to the vagina than on the side of the bladder or urethra. This method is technically challenging, largely as a result of the limited exposure to the critical area of the confluence. Early results produced an isolated and separate vaginal opening that was cosmetically unappealing. Additional problems related to vaginal stenosis have been reported and may be due to tension created by attempts to mobilize a relatively thin vagina all the way to the perineum.[28]

Exposure

Much of the difficulty with pull-through vaginoplasties is related to exposure of the high confluence, and

modifications have been described to improve the approach to the critical proximal area. Passerini-Glazel in 1989[28] popularized Monfort's transtrigonal approach in which the vagina is approached from a midline incision in the posterior wall of the bladder. It does provide superb exposure to a very high lesion but is usually not necessary. During dissection from below, simple incision of the posterior wall of the entire urogenital sinus from the meatus to the level of the confluence may improve exposure over that achieved when leaving the distal portion intact. Opening of the entire sinus then necessitates subsequent tubularization of the same structure for use as a urethra and theoretically increases the length over which a urethrovaginal fistula may occur. Most such fistula, however, when they occur, do so at the level of the initial confluence where the exposure and repair are most tenuous. Anything done to improve exposure and the quality of the repair at that level may ultimately be advantageous. This extended incision into the sinus is particularly beneficial when the distal anomaly is vagina-like. Such a lesion requires tapering distally to achieve a more normal urethra.

The persistent cloaca is a more complex lesion than a urogenital sinus because the rectum is also involved. Cloacal anomalies are generally approached and repaired through a posterior sagittal incision extending from the coccyx. Once the rectal fistula has been removed and the more proximal rectum mobilized, the patient is left with a urogenital sinus that is nicely exposed through an incision that is much longer in the sagittal axis. Reports do exist of a posterior sagittal approach to a high urogenital sinus with splitting of the rectum either completely or anteriorly.[29] Such exposure is superb but potentially adds morbidity and is generally not necessary. Rink et al[30] encouraged the use of an anterior sagittal prone approach without division of the rectum. This approach provides excellent exposure during the difficult mobilization of the vagina off of the posterior urethra and bladder neck and does not preclude use of an inverted U-shaped incision as described for flap vaginoplasty. The procedure begins with the child supine, and the initial steps of clitoroplasty, if necessary, are performed. Initial dissection onto the posterior aspect of the more distal sinus is begun in the supine position. The patient, prepped from nipple to toes, front and back, is then turned prone. The dissection, with remarkably better visualization after the change in position alone, is continued between the posterior wall of the urogenital sinus and the rectum in the midline. The intact rectum is displaced superiorly with a malleable retractor, and the urogenital sinus is opened well into the vagina (Figure 70.10). The same malleable retractor can then be placed into the vagina to provide excellent visualization anteriorly. Following aggressive anterior vaginal mobilization, the urogenital sinus is closed in several layers over a urethral catheter, creating a neourethra. Generally, several layers of tissue can then be approximated in the midline to separate the vagina and urethra.

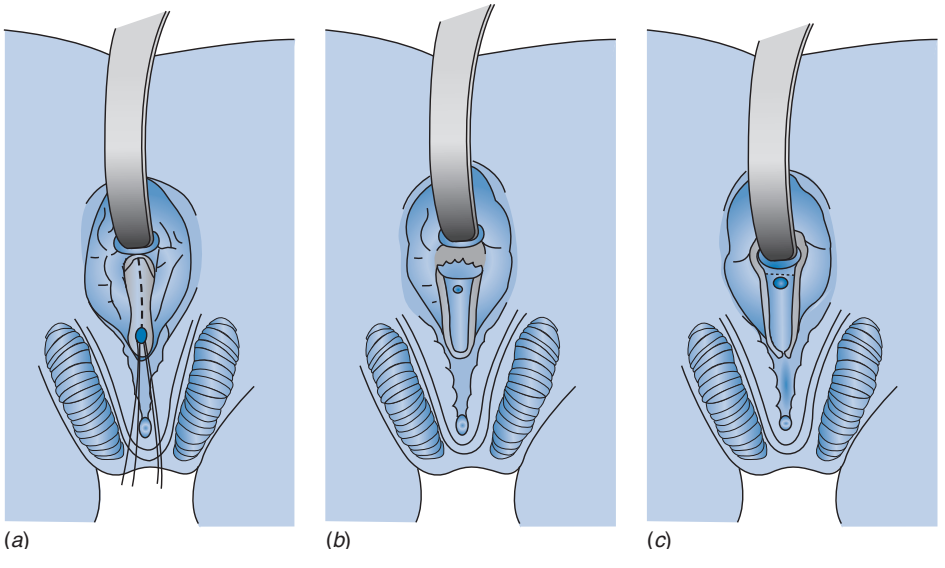

Figure 70.10 Prone exposure to high confluence. (*a*) After creation of a posteriorly based flap, the rectum is retracted to expose the sinus. (*b*) The sinus is opened into the vagina. (*c*) The malleable retractor is placed into the vagina to expose the critical area of dissection (dashed line).

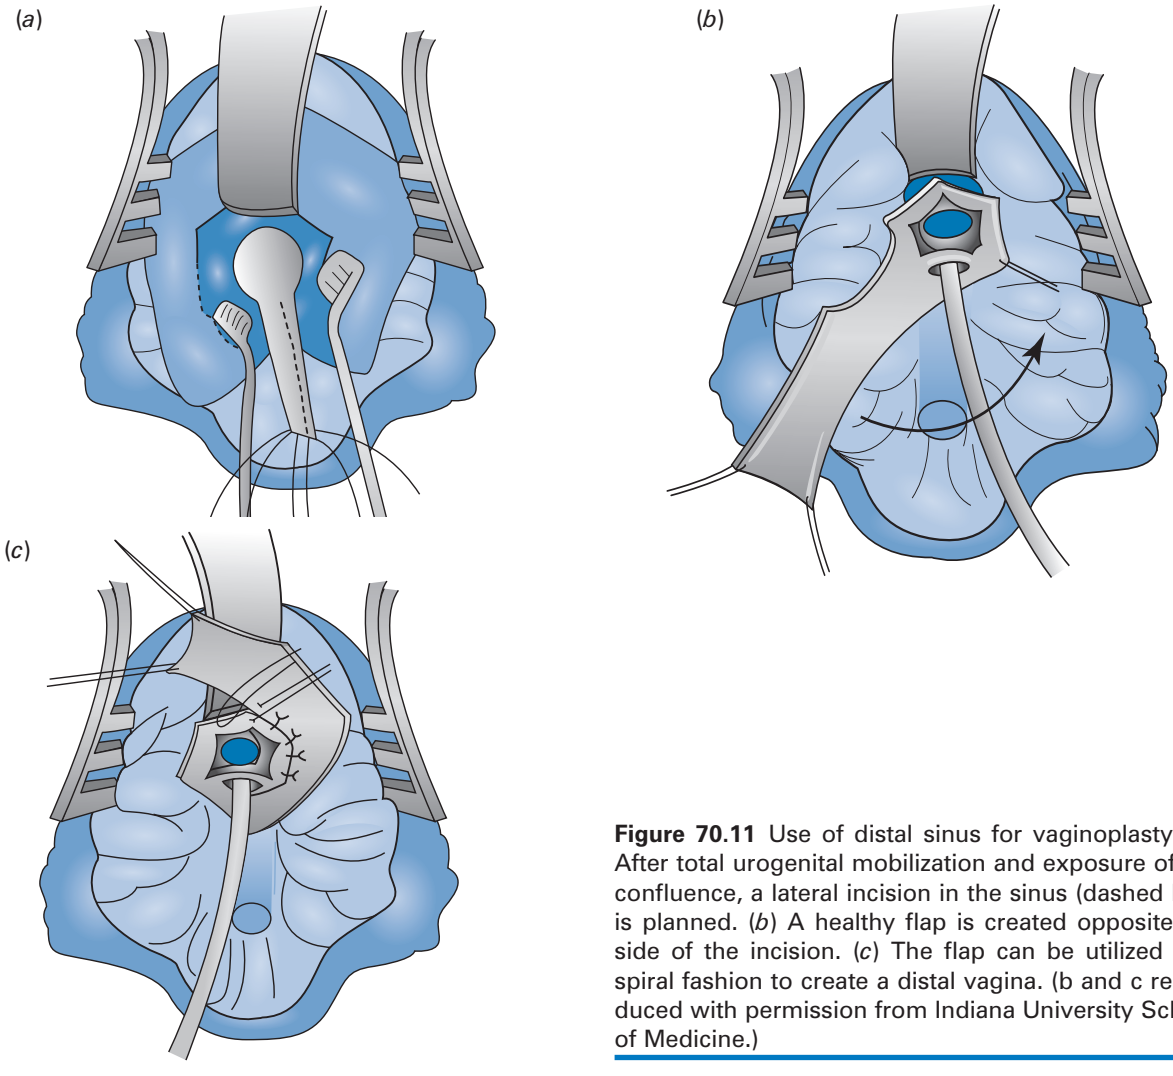

Figure 70.11 Use of distal sinus for vaginoplasty. (*a*) After total urogenital mobilization and exposure of the confluence, a lateral incision in the sinus (dashed line) is planned. (*b*) A healthy flap is created opposite the side of the incision. (*c*) The flap can be utilized in a spiral fashion to create a distal vagina. (b and c reproduced with permission from Indiana University School of Medicine.)

Complex flaps

It is often clear that the short vagina mobilized off of the urethra in a patient with a high-level urogenital sinus may not reach the perineum without tension. The use of flaps to reach the proximal vagina may provide the potential to improve the functional and cosmetic result of pull-through vaginoplasty. Complex flaps of labia majora or buttocks skin from either side may be used to reach the proximal vagina without tension.[31] Such flaps may provide a good result from the standpoint of a functional vagina but can distort the appearance of the introitus. Secondary perineal surgery 6–12 months after initial creation of the flaps may be appropriate to divide the base of such flaps and recreate a more normal appearance of the labia and perineum. Gonzalez[32] used flaps of phallic skin to construct the distal vagina. Passerini-Glazel[28] used the distal urogenital sinus opened anteriorly rather than posteriorly in similar fashion. The sinus was folded back at the proximal end of the anterior incision and combined with phallic skin to tubularize as distal vagina. Such flaps of clitoral skin or distal urogenital sinus may be useful in constructing the anterior vagina in combination with a posteriorly based, U-shaped flap. Rink and Cain[33] have recently described lateral incision into the distal urogenital sinus with spiral construction of a distal vagina that is mucosally lined at the level of the introitus (Figure 70.11).

Total urogenital mobilization

In 1997, Pena described the technique of total urogenital mobilization for repair of urogenital sinus in patients with a cloacal anomaly.[34] Applications for this repair have been expanded to include patients with urogenital sinus abnormalities alone. Such mobilization is generally not necessary for patients with a low confluence, and the best indication for its use may

be patients with a mid-level lesion in whom the level of confluence may be converted to a low one suitable for flap vaginoplasty. The role of total urogenital mobilization for patients with a very high lesion remains to be determined. Total urogenital mobilization may be used in such patients to improve exposure at the critical level of confluence. The urethra and vagina can be mobilized towards the perineum, separated, and the structures released back to a proximal position for reconstruction. Total urogenital mobilization for high lesions with advancement of the confluence to the perineum has also been described; however, long-term validation of the results in such patients need be documented. Potential advantages of this technique include improved cosmesis, easier dissection leading to decreased operative time, and less risk of vaginal stenosis or urethrovaginal fistula.[34] There is no question that this operative technique with advancement is potentially easier as it avoids the difficult dissection between the anterior vagina and proximal urethra or bladder neck; an easier operative approach, however, does not necessarily mean a better long-term result for the patient. Rare patients with a urogenital sinus, particularly those related to the persistent cloaca, may suffer from urinary incontinence or poor voiding. Such dysfunction may be related to the anatomic problem, abnormal innervation, or a combination of the two issues. Circumferential dissection of the urogenital sinus to the bladder neck could potentially exacerbate neurologic problems. Even if it does not do so in the short-term, long-term follow-up of girls with high lesions undergoing total urogenital mobilization with advancement distally will be required to determine the risk of stress urinary incontinence.[35,36] Stress incontinence in patients after such a procedure would probably be difficult to treat.

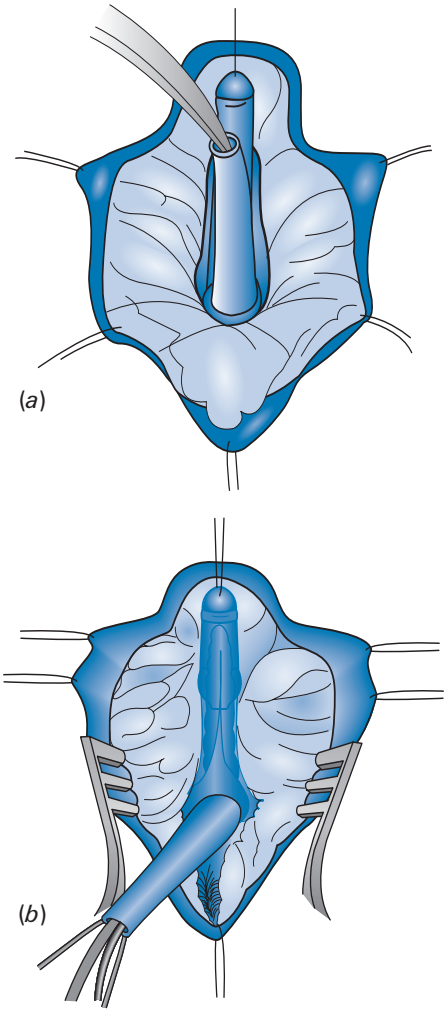

Figure 70.12 Total urogenital mobilization. (*a*) The skin is mobilized and the sinus exposed with a circumferential incision at the meatus. (*b*) The sinus is mobilized from the rectum posteriorly and the corpora anteriorly up to the pubis. (Adapted from Rink RC, Kaefer M,[62] with permission from Elsevier.)

In total urogenital mobilization, the sinus is initially approached from the midline posteriorly, and attachments between the rectum and sinus divided. This exposure may be done from a midline incision or after creation of a posteriorly based flap. The sinus is then circumscribed at the meatus on the clitoris and dissection carried circumferentially from distal to proximal. The distal sinus is carefully mobilized with all spongiosum off of the corpora cavernosa (Figure 70.12). Anteriorly, the ligamentous attachments of the sinus to the pubis are incised, allowing for adequate mobilization to the perineum. It is possible in some cases that anterior dissection may be stopped just short of these attachments.[37] The catheter in the vagina is palpated, identifying the posterior vaginal wall. The vagina is opened posteriorly between stay sutures well through the distal narrow segment. If the vagina reaches the perineum without tension, the sinus can be opened ventrally to create the vestibule. A posteriorly based flap may be useful in some such cases. If the vagina is very high and the urethra very short above the confluence, a decision must be made whether advancement of the intact sinus towards the perineum is appropriate (Figure 70.13). If not, the patient may be turned to the prone position and the vagina separated from the sinus with superb exposure. The distal mobilized sinus may then be incised dorsally or laterally, as previously described,[28,33] and used for vaginoplasty after the more proximal sinus is tubularized as the urethra. The child is usually turned

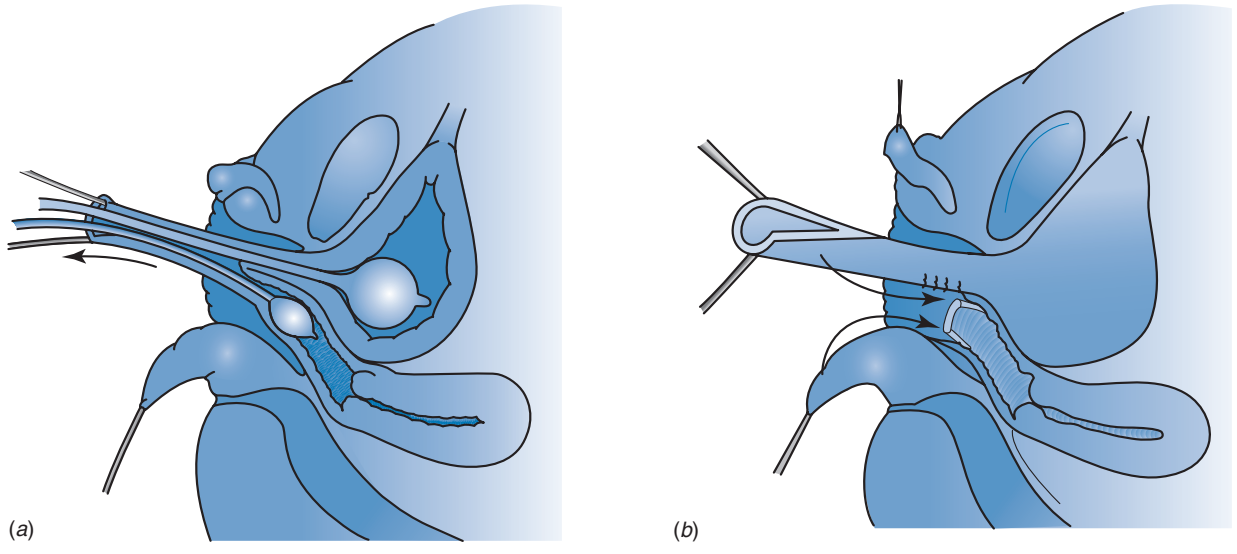

Figure 70.13 Options with total urogenital mobilization. (*a*) After adequate mobilization, the confluence may be advanced to the perineum. (*b*) Alternatively, mobilization allows good exposure for separation of the vagina and urethra. Anterior and posterior flaps may be used for vaginoplasty after releasing the urethra and vagina in a cephalad direction. (Adapted from Rink RC, Kaefer M,[62] with permission from Elsevier.)

back to the supine position to complete the plastic repair of the labia and perineum. Bladder catheter drainage and vaginal packing are usually employed after such complex repairs.

Vaginal replacement

Skin graft

In those patients with absence of the vagina or severe hypoplasia, total vaginal replacement is required. Treatment options have included use of chronic vaginal dilatation,[38] skin grafts,[39,40] rotational flaps,[41] or the use of bowel substitution.[42]

The use of split- or full-thickness skin grafts and rotational flaps remains an option for vaginal replacement. McIndoe described the use of split-thickness skin grafts taken from the thigh and conformed to a cylindrical stent[40] (Figure 70.14). Space is created between the urethra and rectum in which the dermal surface of the skin graft is secured. The vaginal stent is left in place to be removed after a period of 7–10 days. A period of weeks to months of daily vaginal dilatation is usually required to maintain patency and prevent vaginal stenosis. Full-thickness skin grafts have less reliable ingrowth of blood supply but contract less once in place. The full-thickness grafts potentially leave a more obvious cosmetic defect at the donor site. Rotational flaps have been used to create a neovagina. Gracilis myocutaneous flaps,[43] pudendal thigh flaps,[44] labia minora flaps,[45] and flaps raised after tissue expansion have been described.[46] Unfortunately, patients with skin grafts or flaps for vaginal replacement may have problems with lubrication, graft contracture, or dyspareunia, and a need for chronic vaginal dilatation.[47] These difficulties have led to a general acceptance of the superiority of bowel vaginoplasty for replacement, at least among pediatric urologists.

Figure 70.14 McIndoe skin vagina. Split-thickness skin graft is modeled over stent.

Bowel vagina

Advantages of the bowel vaginoplasty include natural lubrication from the intestinal segment, less problems with dyspareunia, and infrequent contracture or stenosis often without any need for routine vaginal

dilatation.[42,48,49] The sigmoid colon is generally preferred for vaginoplasty because of its proximity and ease of mobilization. In addition, the bowel segment does not need to be reconfigured. A segment of ileum, if more mobile, may also be useful but may require folding in an older patient.

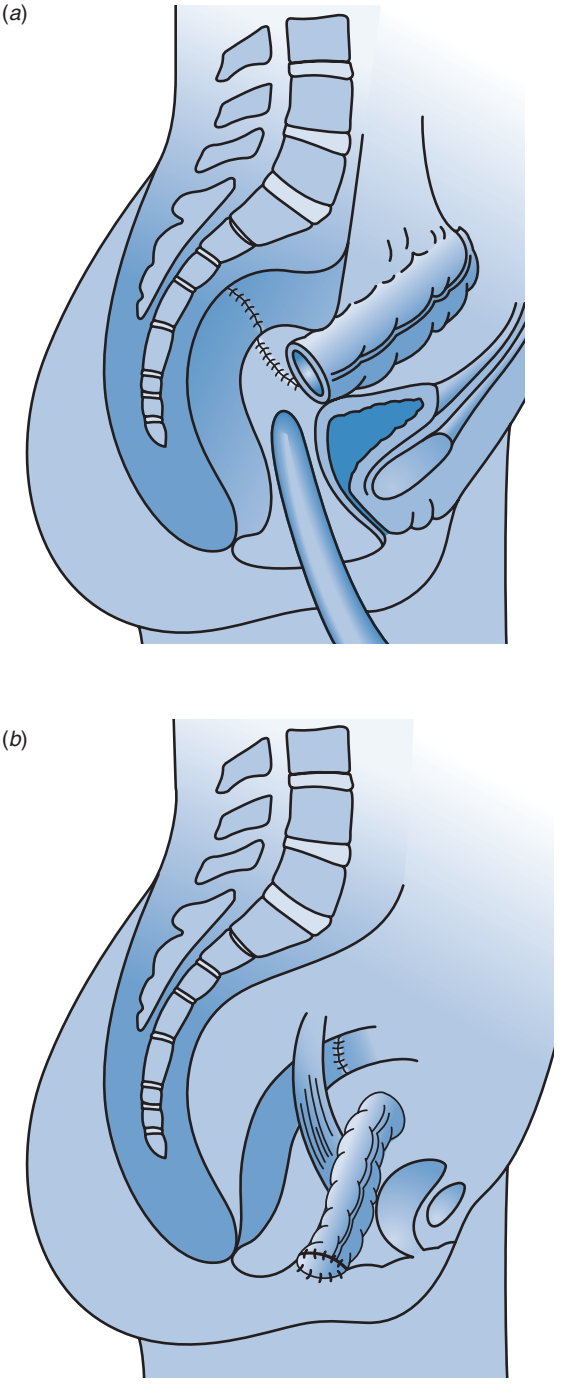

Figure 70.15 Sigmoid vaginal replacement. (*a*) A short segment of colon is isolated and space created from below. (*b*) The bowel vagina is secured in place. (Adapted from Rink RC, Kaefer M,[62] with permission from Elsevier.)

The patient is placed in a modified, low lithotomy position with careful support of the lower extremities to avoid neuropraxia. This position allows for simultaneous abdominal and perineal approach by two surgeons. Through a low Pfannenstiel incision, the sigmoid is identified and evaluated for mobility. An 8–12 cm segment of sigmoid colon is identified and isolated with a window in the mesocolon at either end (Figure 70.15). A short segment is utilized because redundancy in length often results in eventual prolapse at the perineum. Bowel continuity may be reestablished with a stapled or hand-sewn anastomosis. Simultaneously, a second surgeon may perform perineal dissection by developing space between the bladder and rectum to the level of the peritoneal reflection in the cul-de-sac. Palpation of a catheter in the urethra aids in identification of the proper plane. The peritoneum is incised from above and an adequate space created bluntly using a finger initially and then larger dilators. Care must be taken that the space is adequate along the entire length, particularly at the level of the pelvic floor. If an ileal segment is to be used, it is generally opened on its antimesenteric border and folded into a U configuration. Either segment of bowel is checked for viability. Minimal tension at the distal end of the segment reaching to the perineum may not be problematic and may, in fact, help avoid future prolapse. Extreme tension on the mesentery of the bowel segment should be avoided whether using ileum or sigmoid colon. If such tension exists, creation of larger windows in the mesentery may be helpful, although careful identification of mesenteric vessels is critical. Serial transverse myotomies in the isolated sigmoid colon segment may also aid in lengthening of the segment. An inverted U-shaped perineal flap is often used to avoid the appearance of circumferential bowel mucosa at the introitus. The mobilized bowel segment is approximated to the perineal skin, skin flaps, or the remnant of the native vagina with absorbable suture. The neovagina is packed with antibiotic-soaked gauze, which is removed after several days of healing. Irrigation of the bowel segment to avoid accumulation of excess mucus is then begun.

Other procedures

Gonadectomy

A thorough chromosome evaluation is mandatory at the time of initial diagnosis in children with ambiguous genitalia. The presence of all or part of the Y chromosome in patients with disorders of gonadal

differentiation places them at increased risk for development of gonadoblastomas and other germ cell tumors.[50,51] Bilateral gonadectomies in such patients are typically performed in the first several years of life; however, no consensus exists in regards to the optimal timing. We have recently noted bilateral gonadoblastomas in a patient with pure gonadal dysgenesis at 6 months of age and prefer early excision. Gonadectomies are also performed in children with severe feminizing male pseudohermaphroditism who have undergone gender conversion. Laparoscopic excision may minimize morbidity and improve the cosmetic result; it also allows for therapeutic visualization of the abdomen, pelvis, and accessory sex organs. Longitudinal biopsy of the gonads may be appropriate in some patients for diagnosis or prior to excision.

Reconstruction for male pseudohermaphroditism

Male pseudohermaphroditism occurs when there is impaired genital differentiation of an XY male with developed testes and may result in a wide range of male and female phenotypes. Treatment of these children must be individualized, and appropriate surgical intervention may include relatively minor hypospadias repair, orchidopexy, or major genital reconstruction including gender conversion. A detailed discussion of the treatment of these patients is found in Chapter 68.

Results of reconstruction

Quality reviews documenting long-term results following feminizing genitoplasty or vaginoplasty in the setting of a urogenital sinus are lacking, particularly any with careful consideration to the initial anatomy or the surgical technique employed. Clitoral nerve conduction studies have identified preservation following clitoral reduction techniques and are encouraging in regards to ultimate clitoral function.[52] Work evaluating orgasm and sexual satisfaction following such reconstruction is rudimentary at best.

More studies have evaluated the vagina after reconstruction in terms of more obvious complications such as vaginal stenosis or urethrovaginal fistula. Studies evaluating the ability of the vagina to accommodate sexual intercourse after such reconstruction have provided sobering results. Jones and colleagues have noted that 30% of patients required surgical revision after initial vaginoplasty in order to achieve satisfactory intercourse,[53] and Azziz et al reported satisfactory coitus in only 62% of patients 20 years following vaginal reconstruction in patients with CAH.[54] Many of those patients, however, had required secondary or tertiary procedures to correct stenosis at the introitus.

Early vaginoplasty may be a factor in the development of vaginal stenosis. Sotiropoulos et al noted that all of their patients operated upon in a prepubertal period required revision of their introitus at a later date.[55] Bailez and colleagues, as well as Azziz et al, noted more revisions among children in whom vaginoplasty was performed prior to 1 year of age.[10,54] These older series included a wide range of patients with variability in the severity of the initial anomaly or even in the surgical techniques that were employed in their repair. It is possible that newer techniques for exposure, tissue handling, and use of flaps for vaginal reconstruction may change the surgical outcomes for the better; however, only long-term follow-up will determine if that is indeed the case. Careful attention must also be paid to defining the severity of vaginal stenosis after reconstruction. Many stenoses may be minor and only result in the necessity for a minor revision usually involving modified Z-plasty at the level of the narrowing. Such secondary procedures are less troublesome than the major rotational flaps that might be required for severe, extensive stenosis. The difference between the two procedures has not always been well indicated in historic series.

The role of routine vaginal dilatation in an attempt to avoid vaginal stenosis remains unclear. Routine dilatation or calibration may help some patients avoid stenosis if done regularly, particularly in patients destined to develop minor stenosis. It is less likely that routine dilatation will avoid problems in patients headed for extensive fibrosis and stenosis. It is quite possible that long-term vaginal dilatation or calibration may cause some psychological trauma for the patient or parent. Proponents of delayed vaginal reconstruction would suggest that the need for dilatation or secondary surgical revision demonstrates the advantages of later reconstruction. It is clear that vaginoplasty, particularly for a patient with a moderate or high confluence urogenital sinus, is a major surgical procedure in an older patient. Such a procedure may likewise have a profound psychological impact on the patient and still carry risk for stenosis or other complications.

Urethrovaginal fistulae can occur following reconstruction of the urogenital sinus but fortunately are much less common than vaginal stenosis. Careful, yet

aggressive, separation of the vagina and urethra allows adequate reconstruction of both structures and interposition of layers of tissue in between in order to minimize the risk of fistula. The most likely place to develop such a fistula is the area of the initial confluence. Modern techniques to improve exposure and use more effective flaps for vaginoplasty should lower the risk of fistula formation. Total urogenital mobilization without separation of the proximal urethra from the vagina should carry virtually no risk for the problem.[34]

Controversy

Historically, the decision of gender assignment has been made shortly after birth by the parents in consultation with a multispecialty team. This choice involves many factors and includes genotypic sex and the functional potential of gonadal tissue, reproductive tracts, and the external genitalia. Such a scheme is still utilized in most centers. Sex assignment in infancy has been advocated by many as it allows for early and consistent gender-specific social interactions throughout childhood. Support for this school of thought came from the observations and work of Money and investigators.[56–59] Partially driven by older patients unhappy with their sexual development, some of the lay and medical community have more recently questioned the timing and need for reconstructive surgery. Proponents of waiting and allowing for full participation in such decisions by the patient at a later age have appeared and gained support.[60,61] A few authors have called for a moratorium on genital reconstructive surgery until these concerns can be appropriately addressed.

It is beyond the scope of this chapter to address all of the moral, ethical, and gender identity issues involved with female genital surgery. It is important to note that, while no universal practice policy has gained acceptance, it is incumbent upon the surgeon interested in such problems to be well aware of these issues and discuss them openly with patients and parents. Well-planned, long-term outcome studies are needed to address these problems and should lead to further refinement in the timing and techniques of genital reconstruction.

Conclusions

Significant strides have been made in surgical outcomes of patients with urogenital sinus abnormalities and intersex states. Evaluation of previously employed techniques, improved understanding of genital anatomy, and a greater sensitivity to the complex nature of genital innervation have led to improvements in terms of both cosmesis and, perhaps, function. Although complications, the most common being vaginal stenosis, may still occur following female genital reconstruction, the ultimate expectation for the patient and family should be normal or nearly normal appearing and functioning genitalia. Even when such a result is achieved, the underlying problem and process of reconstruction often have a profound psychological impact on the patient, particularly in terms of sexual identity. It remains to be determined how the best functional endpoint can be achieved for the patient with the least morbidity in that regard.

Hypospadias

71

Warren T Snodgrass, Aseem R Shukla, and Douglas A Canning

Introduction

Hypospadias occurs following abnormal development of the penis. The urethral meatus in hypospadias may be proximal to its normal glanular position anywhere along the penile shaft, scrotum, or perineum. A spectrum of abnormalities including ventral curvature of the penis (chordee), a 'hooded' incomplete prepuce, and abortive corpora spongiosum are commonly associated with hypospadias.

John W Duckett Jr, the former chief of the Division of Urology at the Children's Hospital of Philadelphia (CHOP) and a pioneer in hypospadias repairs, coined the term hypospadiology. Today, hypospadiology encompasses a continuously evolving and expanding discipline. Whereas modern experiments have only recently begun to yield a deeper understanding of the genetic, hormonal, and environmental basis of hypospadias, the quest for a surgical procedure that consistently results in a straight penis with a normally placed glanular meatus has eluded surgeons for over two centuries. Advances in the understanding of the etiology of hypospadias and the current approaches to the correction of hypospadias to provide a cosmetically and functionally satisfactory repair are the focus of this chapter.

Etiology

Hypospadias results from partial or complete failure of urethral folds to form throughout their normal length or a failure of the folds to close distally if they have formed. The extent of the closure determines the position of the urethral orifice.

A unifying etiology for hypospadias remains elusive. Hypospadias probably results from multiple factors. The hypospadiac anatomy appears consistent with incomplete embryologic development as a result of:

- abnormal androgen production by the fetal testis
- limited androgen sensitivity in target tissues of the developing genitalia
- premature cessation of androgenic stimulation due to early atrophy of the Leydig cells of the testes.[1,2]

Endocrine factors

A number of writers have suggested that hypospadias represents a mild form of intersexuality. It could represent one end of a spectrum, the other of which is a completely feminized male.[3] Hypospadias may result from an endocrinopathy in which there is a disruption in the synthetic biopathway of androgens. More than just a focal malformation, hypospadias may be a local manifestation of a systemic endocrinopathy. A qualitative androgen receptor abnormality or defects at a post-receptor level may explain the defect in some boys with hypospadias. For example, the blunted response to human chorionic gonadotropin (hCG) injections seen in many boys with hypospadias may suggest a mutation in the luteinizing hormone (LH) receptor in the testis or perhaps an increase in receptor numbers because of the previous stimulation.[4] In a study of 15 boys under 4 years of age with severe hypospadias, Allen and Griffin diagnosed 11 boys with six distinct endocrine-related abnormalities. The most consistent finding was a subnormal testosterone response to hCG stimulation in seven boys. The authors believe their findings may represent a delay in the maturation of the hypothalamic–pituitary–testicular axis.

Genetic factors

Hypospadias may have a complex genetic background, with gene expression acting in concert with environmental factors. The familial rate of hypospadias is approximately 7%, which reflects a non-familial, sporadic finding in most cases. Recent studies have suggested a role for müllerian inhibiting substance (MIS) in the etiology of hypospadias. There is an inverse relationship between MIS and testosterone, and this may be related to the MIS inhibition of cytochrome P450c17 CYP17, the enzyme that catalyzes the committed step in testosterone synthesis.[5] Indeed, MIS may directly inhibit testosterone production by suppressing the *CYP17* gene.[6] Abnormalities of other genes such as fibroblast growth factor-10 (*FGF-10*) have also been shown to result in hypospadias.[7]

Normal sexual differentiation depends on testosterone and its metabolites as well as functional androgen receptors. Despite a correlation of certain clear defects in the androgen metabolism pathway and hypospadias, as in the 5α-reductase II (5αRII) defect (mutation in *SRD5A2* gene on chromosome 2), such associations have been limited to few cases – underlining the importance of seeking other genetic explanations for this congenital defect.[8]

Environmental factors

The incidence of hypospadias is increasing. One possible explanation is environmental contamination. Insecticides, pharmaceuticals, and plant estrogens contain estrogenic ingredients. Manufacturers of cans used in the canned food industry coat the inside of the cans with plastics known to contain estrogenic substances.[9] These substances are ultimately present in freshwater and seawater in trace amounts that bioaccumulate and concentrate in higher organisms of the food chain. For this reason, predators at the top of the food chain, such as large fish, birds, sea mammals, and humans, accumulate high levels of estrogenic environmental contaminants. Thus, humans and wild animals are constantly exposed to estrogenic compounds that are known to disrupt reproduction – the so-called endocrine disrupters.[7]

Epidemiology

The incidence of hypospadias varies geographically. Prevalence ranges from 0.26 per 1000 births (both male and female births) in Mexico to 2.11 in Hungary and 2.6 per 1000 live births in Scandinavia.[10] A recent study found the rate of hypospadias in a 2-year prospective study to be 38 in 10 000 live births in Netherlands, a number six times higher than previously recorded.[11] Sweet and colleagues reported a much lower incidence in Sweden of 1 in 1250 live male births.[12]

In 1997, two independent surveillance systems in the United States – the nationwide Birth Defects Monitoring Program (BDMP) and the Metropolitan Atlanta Congenital Defects Program (MACDP) – reported a near doubling of the incidence of hypospadias when compared with immediately preceding decades.[13] The incidence of all types of hypospadias increased from 20.2 to 39.7 in 10 000 live male births during the period from 1970–1993; i.e. one in every 250 live male births was a boy with hypospadias (measured by BDMP). MACDP reported a rise in the severe hypospadias rate of between three- and five-fold. These rising trends, however, may simply reflect earlier diagnosis or an increase in reporting to registries of congenital defects. The increased reporting of more proximal than distal hypospadias cases, however, refutes the argument that these findings simply represent more frequent reporting of minor cases.[14]

Recent studies have linked the rising rate of hypospadias in boys born prematurely and small for gestational age, boys with low birth weight, and boys born to mothers over 35 years of age.[15–17] Roberts and Lloyd noted an 8.5-fold increase in hypospadias in one of monozygotic male twins, compared with singleton live male births.[18] This may suggest a discrepancy in the supply of hCG to the fetus where a single placenta is unable to meet the requirements of two developing male fetuses.

Embryology of hypospadias

The genital tubercle appears during the 4th week of gestation as anlagen for development of either the clitoris or penis. Endodermal cells from the cloaca migrate along its ventral midline surface to create the urethral plate, while proliferating mesenchyme on either side establishes the urogenital folds. Subsequent phallic development is dependent upon androgenic stimulation during a critical period from the 9th to 12th weeks. 5αRII in the genital tubercle catalyzes the conversion of testosterone, produced by fetal Leydig cells within the testes, to dihydrotestosterone (DHT). DHT then binds to androgen receptors to initiate a cascade of downstream effects.

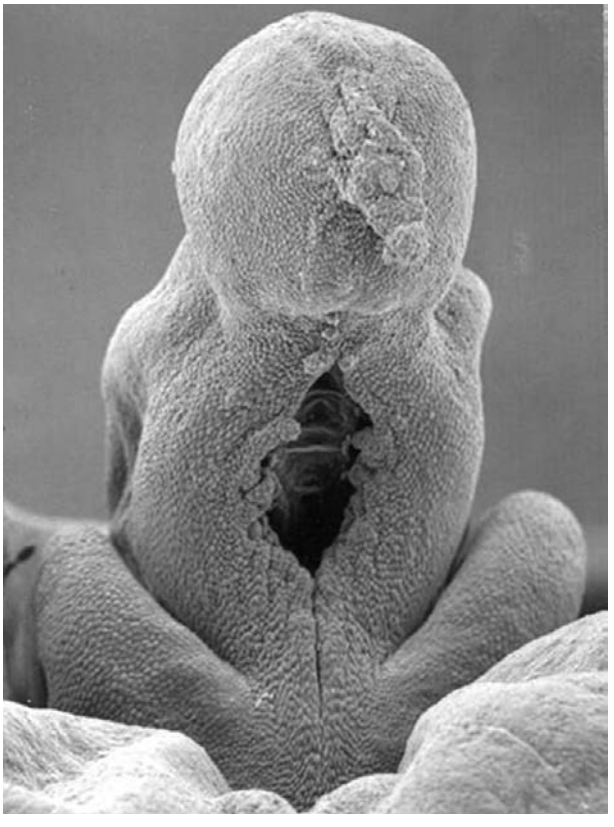

Figure 71.1 Scanning electron micrography demonstrates fusion of the urethral folds proximally while the distal urethral plate remains open before tubularization.

Androgen stimulation causes the genital tubercle to elongate and the urogenital (urethral) folds to migrate toward the midline and fuse, enclosing the urethral groove (Figure 71.1). This process moves proximally to distally creating the pendulous urethra. Some clinicians have disputed the current theories of the formation of the glanular urethra. One theory holds that ectoderm from the glans surface migrates inward to contact the distal urethral plate and establish continuity with the urethra.[19–22] Alternatively, the endodermal plate may continue to canalize distally until surface ectoderm is reached.[23]

Gene knockout studies in mice have further characterized the process of urethral plate tubularization. Concerns that this animal model, with its postnatal formation of an os penis, poorly represent human development were addressed by Baskin et al,[24] who determined that the basic processes of genital tubercle and urethral development were analogous in the two species. Specifically, Baskin's group noted urethral tubularization in mice also extends from proximal to distal, with formation of a urethral seam where the two sides fuse. A proposed mechanism for hypospadias is failure of ventral plate fusion, and *FGF-10*-deficient mice with abnormal seam development have an opened urethra resembling hypospadias[25] (Figure 71.2). Mesenchyme along the midline during seam formation normally expresses this signaling molecule and therefore seems to play an important role in normal urethral development in mice.

In humans, as the plate tubularizes, mesoderm within the urethral folds differentiates into corpus spongiosum, which fuses with the glans distally. Mesoderm also forms the corpora cavernosa. Development of the penis apparently proceeds at different

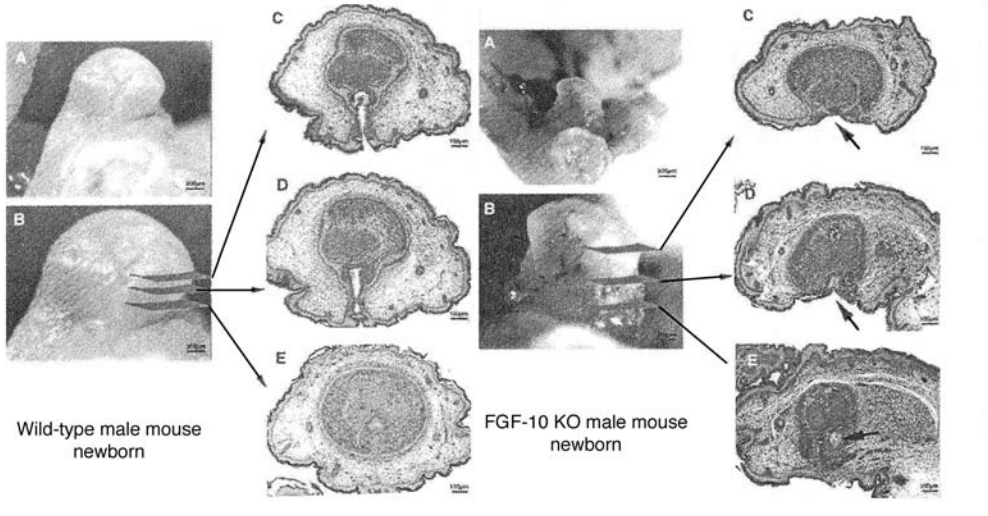

Figure 71.2 Gross and histologic comparison of urethral development in normal wild-type mice versus fibroblast growth factor-10 (*FGF-10*) gene deletion 'null' mice. Normal mouse genital tubercle formation with a distal urethral meatus contrasts with a proximal urethral opening in the knockout model. Histologic sections demonstrate abnormal distal urethral seam formation associated with *FGF-10* deletion.

rates along the ventral vs dorsal surfaces, resulting in temporary ventral curvature.[20,26] Similarly, the dorsal prepuce extends beyond the glans before the ventral aspect, which follows closure of the urethral groove. Midline fusion of the ventral prepuce ends in the frenulum.[27]

The dorsal penile nerve provides sensation to the penile shaft and glans running under Buck's fascia along the surface of the tunica albuginea of the corpora cavernosa. The 12 o'clock position in the dorsal midline is devoid of nerves, which extend longitudinally from 1 and 11 o'clock circumferentially to the borders of the corpus spongiosum.[28] Additional innervation from the perineal nerve supplies the frenulum.[29]

Hypospadias is the result of arrested penile development. Consequently, the urethral opening can occur from the perineum, where urethral fold fusion begins, to the glans. The urethral plate extends from the hypospadiac meatus to the tip of the glans. This plate is the residuum of tissues that in the normal case would have completed urethral tubularization. The glans does not fuse ventrally under the meatus, resulting in two 'wings' on either side of the urethral plate. Along the shaft, the corpus spongiosum also diverges along the lateral margins of the urethral plate to join ipsilateral glans wings. Typically, there is no frenulum, and ventral preputial development is incomplete, whereas the dorsal aspect is formed, covering the dorsal glans. In addition, the penis may demonstrate persistent ventral curvature, commonly referred to as 'chordee.'

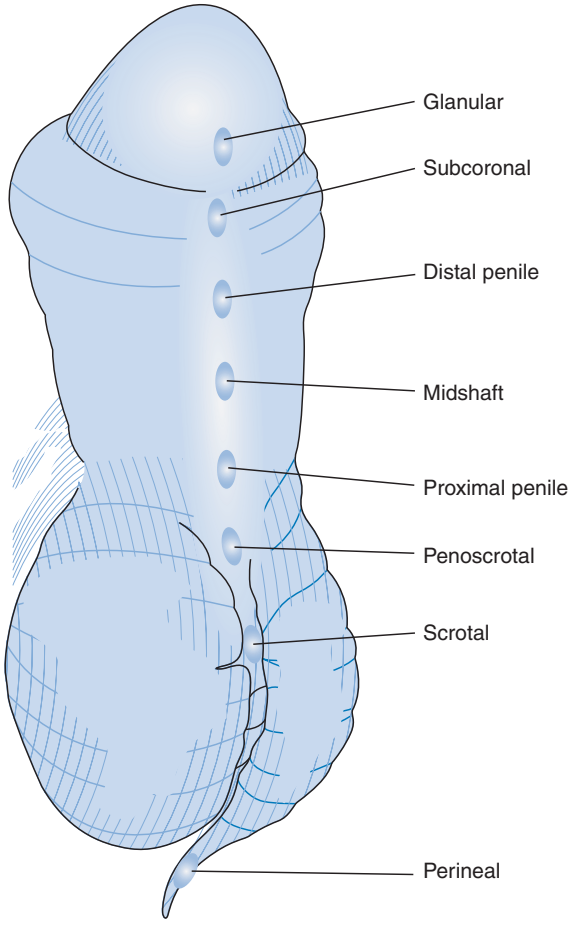

Figure 71.3 Classification of hypospadias based on anatomic location of the urethral meatus. Anterior, or distal, hypospadias is the most commonly encountered variant.

Presentation

The abnormal prepuce and ventral glans tilt of the newborn penis usually signifies the presence of hypospadias. Further examination of the penis typically reveals the proximally displaced urethral orifice that is often stenotic in appearance, but almost never obstructive. An exception is the megameatus variant of hypospadias. In this unusual case (6% of all distal hypospadias presentations), an intact prepuce is present. The diagnosis in usually not made until after a routine neonatal circumcision is completed.[30]

The location of the meatus and extent of ventral curvature, or chordee, should be determined. In some instances, multiple pinpoint dimples may be present on the surface of the urethral plate in addition to the hypospadiac urethral meatus. The meatus is always the most proximal of these defects and physical examination or passage of a probe can confirm this. Surgeons classify meatal position as anterior (distal), middle, and posterior (proximal), with more anatomically specific subgroups being further applied (Figure 71.3). The meatus is located on the glans or distal shaft of the penis in approximately 70–80% of all boys with hypospadias; 20–30% of boys with hypospadias have the meatus located in the middle of the shaft of the penis. The remainder of the boys with hypospadias have more severe defects, with the urethral meatus located in the scrotum or even more proximally on the perineum.[31]

Increased understanding of the endocrinology of hypospadias has corroborated the clinical association of hypospadias with intersex states.[32,33] As such, boys with severe proximal hypospadias and those with hypospadias and cryptorchidism should undergo karyotype analysis and an intersex evaluation as indicated. The unilaterality or bilaterality of crypt-

orchidism concomitant with hypospadias does not predict the diagnosis of an intersex state.

A complete penile examination requires independent evaluation of penile length. If the glans size precludes adequate surgical repair of hypospadias, androgen stimulation with hCG has been shown to increase penile length and may also move the meatus to a relatively more distal position as the shaft elongates.[34]

Timing of surgery

A report from the American Academy of Pediatrics (AAP) in 1996[35] suggests the optimal time for elective male genital surgery is between 6 and 12 months. However, significant phallic growth is apparent in most infants by 3 months, presumably due to the postnatal testosterone surge that peaks around the 2nd month. Furthermore, from an anesthetic perspective, day surgery is safely accomplished after the 50th gestational week.[36,37] Consequently, skilled pediatric urologists may perform hypospadias repair in healthy term babies as early as 3 months. There may be advantages to early surgery. Leichty et al have shown near-scarless wound healing following fetal surgery.[38,39] Our experience has been that younger infants develop less scarring following surgery than do older children.

Based upon consideration of emotional, cognitive, and psychosexual factors, pediatric urologists now recommend that hypospadias surgery be completed by 15 months.[37] This means that in severe cases the first surgery should occur by 4 months. By 30 months, awareness of the defect occurs, and school-age boys with hypospadias are more likely to exhibit gender-atypical behavior than those with normal genitalia.[40]

Hormonal stimulation

The role of supplemental hormonal therapy before hypospadias surgery is not clear. No study has randomized boys to preoperative stimulation with hormone or placebo. Typical indications for administering hormones are a small-appearing penis and/or glans and ventral curvature. Some also advocate its use prior to repeat surgery to increase availability and vascularity of penile skin. The means of administration include topical ointments applied to the penis and intramuscular (IM) injection.

Citing concerns that topical applications potentially have inconsistent absorption, Gearhart and Jeffs[41] reported that 2 mg/kg testosterone enanthate given IM 5 and 2 weeks preoperatively resulted in a 50% increased penile size in all cases. It should be noted that of their 36 hypospadias patients, 27 had midshaft or more distal hypospadias while only three patients had penoscrotal defects and six other patients awaited reoperation. The mean change in penile length was from 4.7 cm to 7.4 cm. In another series, 25 patients aged 6–18 months, including 15 with penoscrotal and two with perineal hypospadias, received testosterone enanthate 25 mg IM once monthly for 3 months before surgery.[42] A mean increase in penile length from 2 cm to 2.4 cm and glans circumference from 2.7 cm to 3.7 cm occurred in 92% of cases.

Efficacy of topical vs parenteral testosterone was compared in a randomized study of 26 patients with hypospadias and penile size more than two standard deviations below normal.[43] In this study, the investigators applied testosterone enanthate 2 mg/kg/week twice daily or gave the same dose IM once weekly for 3 weeks. Mean increased penile length was approximately 1 cm, regardless of dosage form. There was no difference in measured serum testosterone levels, although two patients receiving topical preparations exceeded the normal level of 10 ng/ml, possibly due to excessive application by their parents, causing the authors to conclude topical therapy is effective but less well controlled than parenteral treatment.

Koff delivered a 5-week course of hCG at 250 IU or 500 IU given IM twice weekly, to 12 boys <1 year old and 1–5 years old, respectively, with proximal hypospadias and ventral curvature.[44] Penile length increased in all cases from a mean 1.7 cm to 3 cm, and the authors subjectively noted decreased severity of curvature. Since no patients had parenteral testosterone, it is unclear if there is benefit to this protocol with its increased number of injections.

Side effects during hormone therapy include aggressive behavior and pubic hair growth, which regress after treatment stops. The increased penile length obtained by stimulation also recedes. Studies monitoring linear growth and bone age have demonstrated no adverse effects.[45]

Evolution of hypospadias surgery

Hypospadias repair began in the late 1800s, with an emphasis on correcting proximal defects. Both the insights and misconceptions early surgical pioneers

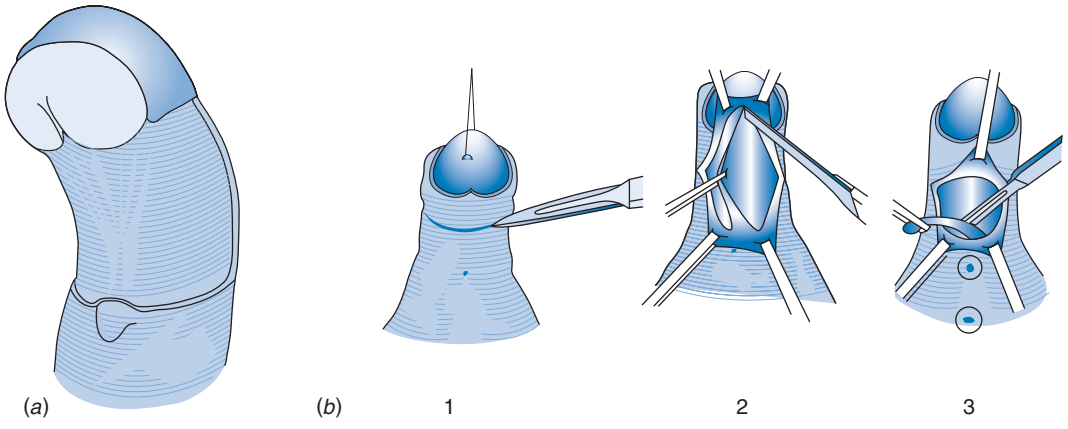

Figure 71.4 (*a*) Traditional concept of chordee tissues representing fibrous remnants of dartos fascia, Buck's fascia, and corpus spongiosum extending in a fan shape from the meatus to the glans. (Reproduced from Hinman,[46] with permission.) (*b*) Duplay's method to straighten the penis. A transverse skin incision was made across the urethral plate (1), fibrous subcutaneous tissues were excised (2), and then the skin was closed vertically (3).

derived from their experience with severe hypospadias continue to influence hypospadiology today. The goals of surgery have been clear from the outset – i.e. straightening ventral curvature and extending the shortened urethra distally – but the plethora of operations described attests to the difficulties in achieving these aims.

Pare originally attributed penile curvature to ligaments tethering the undersurface of the penis in the 1500s. He eventually coined the term 'chordee.' A transverse skin incision across the urethral plate provided access to resect these fibrous bands (Figure 71.4), and further displaced the meatus proximally. Over time, surgical excision of presumably 'dysgenetic' tissues became more extensive. For example, in the 1950s Byars[47] advised that fibrous elements be removed from the entire ventral half of the penis along the corpora cavernosa reaching into the intercorporeal septum, whereas Devine and Horton[48] subsequently wrote that meticulous dissection of the chordee should leave the surface of the corpora 'clean and glistening.'

Despite van Hook's suggestion in 1896 that downward curvature 'is largely due to lack of development of the corpora cavernosa,'[48] it was not until 1952 that Smith and Blackfield mounted a serious challenge to the prevailing belief that chordee tissue required excision.[50] They reported straightening of the penis merely by degloving the penile shaft via an incision just distal to the meatus, without need to resect 'phantom' ventral bowstrings. Allen and Spence[51] later observed a circumscribing incision made proximal to the meatus was also effective for distal hypospadias, and did not further displace the urethral opening. In 1974 corporeal injection was described as a means for intraoperative assessment of penile curvature,[52] which until this time could only be assessed by traction on the glans. Subsequently, Duckett[53] found extensive chordee resection did not reliably straighten the penis, adding strength to the argument that curvature persisting after the penis is degloved indicates ventral corporeal disproportion. Finally, Kaplan and Lamm[26] and Baskin et al[28] examined fetal specimens with hypospadias, finding no fibrous bands, whereas Snodgrass et al[54] reported subepithelial biopsies of the urethral plate revealed only well-vascularized connective tissues without fibrosis.

In 1965 Nesbit[55] presented three cases of chordee without hypospadias in which bending was corrected using dorsal corporeal plication, a technique previously described by Physick in 1844. Ironically, Nesbit reported his patients were unusual in that they had curvature without ventral fibrous bands, leading him to ascribe their condition to 'rare' corporeal asymmetry. Nevertheless, as the practice of extensive chordee resection lessened, popularity of 'Nesbit plication' increased, especially for mild degrees of curvature. Alternatively, some surgeons began to use ventral incision and grafting of the corpora to correct corporeal disproportion, especially when bending is severe.

Surprisingly, urethroplasty using the urethral plate – which so dominates current hypospadias surgery – is a new concept dating only from the mid 1980s. Since this tissue was previously thought to consist of epithelium overlying fibrous bands, surgeons often excised it. Consequently, early attempts at urethral reconstruction emphasized skin substitutes and led to a century of creative variations for incorporating pre-

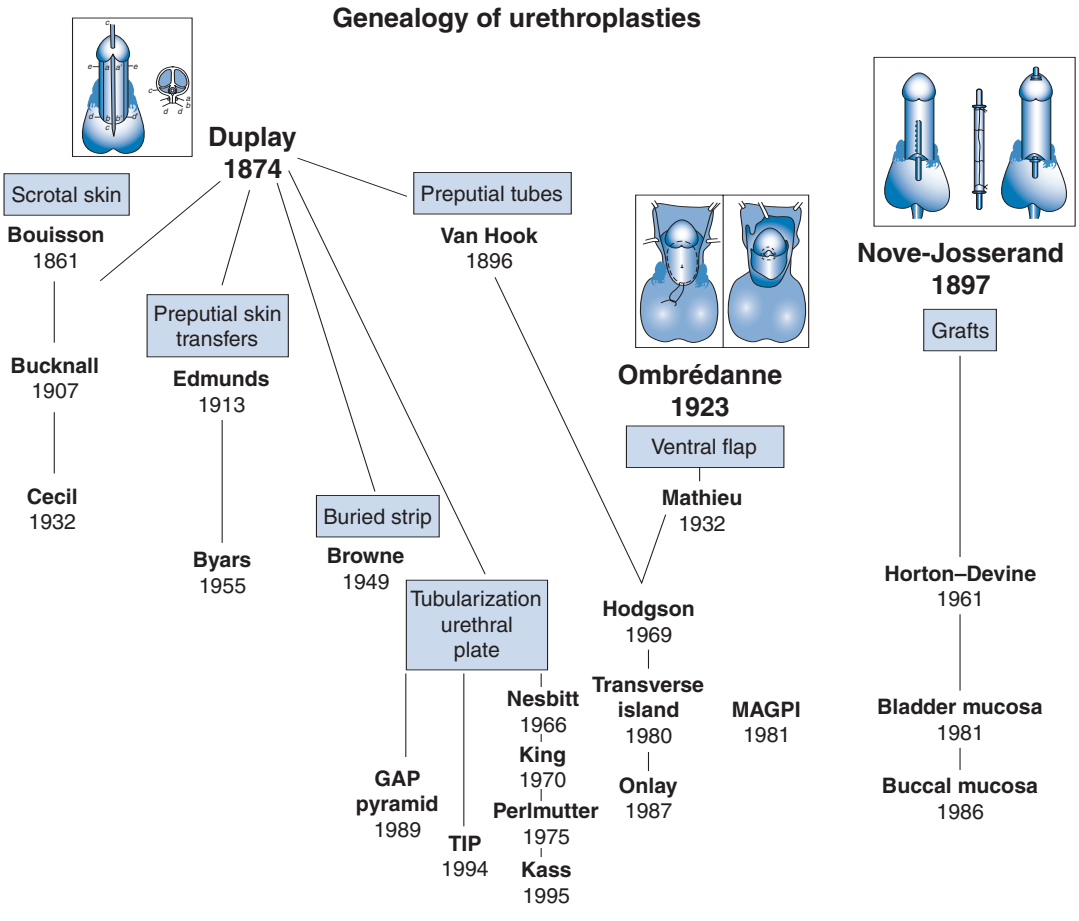

Figure 71.5 Genealogy of hypospadias repairs.

puce, penile shaft skin, scrotum, and extragenital skin as flaps and grafts into the neourethra (Figure 71.5).

Urologists performed the first hypospadias repairs as staged operations, beginning with chordee excision followed by urethroplasty. In 1869 Thiersch[56] described the use of skin flaps to correct epispadias, and his technique using pants-over-vest closure of asymmetric flaps was soon applied to hypospadias by Anger.[57] Duplay favored symmetric incisions to create a skin flap neourethra, but found it difficult to close the overlying wound without a relaxing incision through the dorsal shaft skin. He later described a second procedure cutting narrower ventral flaps to facilitate skin closure without a dorsal incision, but was unable to fashion a neourethra of sufficient diameter. Instead, he simply left a catheter lying on the buried skin strip under the overlying shaft closure, and relied upon epithelialization to complete the urethra.[58] These techniques fell into disfavor until Denis Browne revived Duplay's second method in the 1950s. Today, it is common to speak of the Thiersch–Duplay procedure when a neourethra is tubularized, but historically there was no use of this term until the 1970s.

The apparent need for additional tissues to construct the neourethra and/or resurface the ventral shaft led to the use of the scrotum and prepuce. van Hook[49] was the first to tubularize a preputial pedicle flap, whereas Edmunds[59] in 1913 buttonholed the prepuce and transferred it ventrally to cover the defect created by chordee excision, later rolling the transposed skin into the neourethra. Modifications of these techniques subsequently evolved in the hands of Hodgson, Standoli, Asopa, and finally Duckett, who recognized that he could safely dissect the inner prepuce on a vascular pedicle away from the outer prepuce and dorsal shaft skin. This maneuver improved handling of these flaps, which Duckett first tubularized and then later used as 'onlays' to the urethral plate.

Shaft skin flaps date at least to Ombredanne,[60] who in 1923 reported a meatal-based flap drawn with a purse-string suture into a pouch-like neourethra. A decade later Mathieu[61] refined this concept into a

'flip-flap' that became a mainstay of distal hypospadias repair in the 1980s.

A third pioneer in hypospadias surgery was Nove-Josserand, who used extragenital skin grafts for urethral reconstruction. He tubularized the graft and tunneled it under the shaft skin and through the glans using trocars.[57] Years later, Horton and Devine[62] obtained grafts from the prepuce for primary hypospadias repair, while bladder epithelium and then buccal mucosa were popularized for reoperations when the prepuce was not available.

During the first century of hypospadias surgery many procedures intentionally resulted in a subglanular neomeatus, and there was controversy regarding the need to correct distal hypospadias. The modern era in hypospadiology can be traced to meatoplasty and glanuloplasty (MAGPI), introduced by Duckett in 1981[63] for distal repairs. This operation provided a relatively simple means, with few complications, of improving the appearance of the glans, and led to increased emphasis on the cosmetic outcome of hypospadias reconstruction. Other techniques to repair more severe hypospadias subsequently came under increased scrutiny as the standard for success grew to include not only functional but also cosmetic results.

By the late 1980s nearly all defects could be repaired using the MAGPI, onlay,[64] or tubularized preputial flaps[65] as described by Duckett, although the flip-flap remained popular as a technically simpler alternative to onlay. However, one criticism of both onlay and flip-flaps was the unnatural appearance of the neomeatus, particularly when the urethral plate was flat. It had previously been recognized that urethral plate configuration determined orientation of the neomeatus, as a deeply grooved plate produced a vertical meatus while a flat plate resulted in a horizontal, round opening.[66] Rich et al[67] began 'hinging' the distal lip of the flat plate to achieve a vertically oriented meatus. Snodgrass[68] extended the midline incision deeply along the entire length of the urethral plate and found he could not only fashion a vertical meatus but also he could tubularize the plate without need for additional skin flaps.

Duplay constructed the neourethra from skin, having resected the urethral plate during the first-stage operation to remove chordee. In 1970, King[69] encountered a patient with midshaft hypospadias but no chordee and extended the urethra to the coronal margin by tubularizing ventral skin, including what is now known as the urethral plate (Figure 71.6). He would later modify this approach to bring the meatus

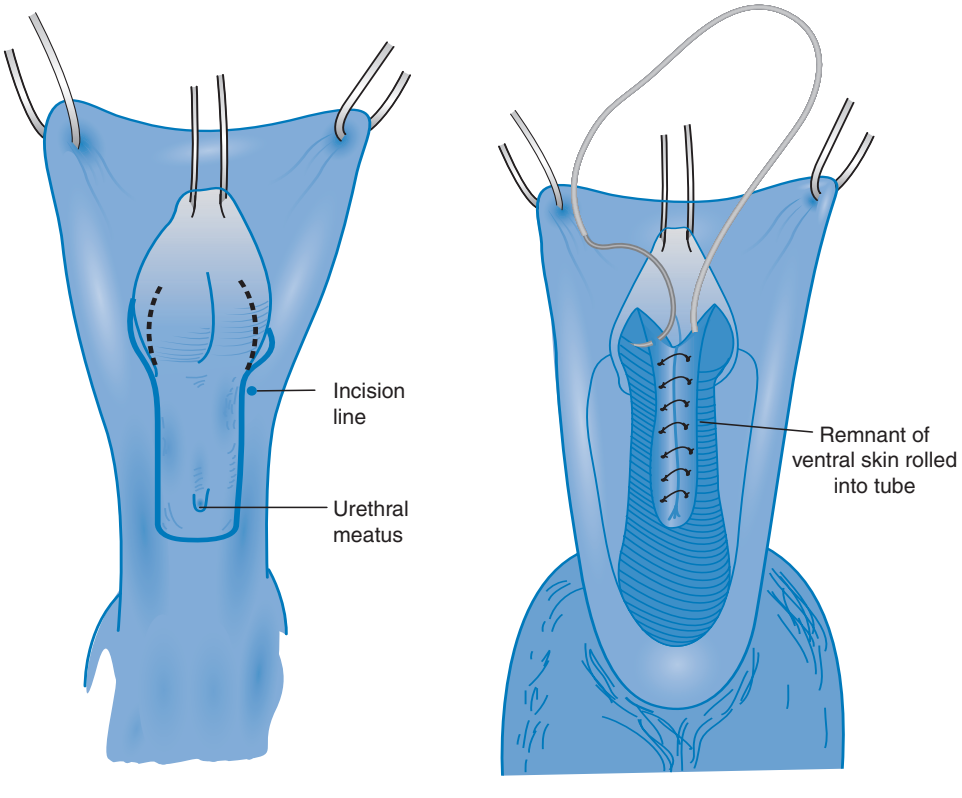

Figure 71.6 Tubularized ventral skin.

onto the edge of the glans, and subsequently, in the late 1980s and early 1990s, others would describe complete tubularization of the plate, especially when it was already deeply grooved.[70,71] Urethral plate incision made tubularization possible even when the plate was flat or only slightly clefted, and the ability to create a vertical and slit-like meatus reliably resulted in its rapid acceptance worldwide.

Surgical repair

The key steps in hypospadias repair include correction of associated ventral curvature, urethroplasty, interposition of a tissue barrier layer between the neourethra and overlying skin closure, and management of the prepuce by either circumcision or foreskin reconstruction.

What follows is a dialogue that represents two schools of thought. The senior authors are friends who are passionate about hypospadias repair, but who do not always agree on the approach to each clinical situation. We have debated these points in the past, and through these debates, which we will share with the reader, we have learned to challenge our ideas and stimulate the commitment to learn even more about this fascinating subject.

Instruments

Increasing experience has demonstrated the applicability of the principles of plastic surgery to hypospadiology. Instruments such as fine scissors, 0.5 mm tooth forceps and Castroviejo needle holders are commonly used with fine 6–0, 7–0, or even 8–0 absorbable sutures to delicately handle tissue and precisely place sutures of adequate purchase. Considerable variation exists among surgeons as to the choice of suture material. We prefer polyglycolic suture material for construction of the neourethra and for subcuticular sutures. We use a glanular stay suture to minimize tissue handling during repair. We don't recommend polydiaxanone (PDS) suture for urethral repair due to its extended absorption time interval and increased urethral stricture rate.[72]

Hemostasis

Hemostasis is achieved with a variety of techniques. A tourniquet placed at the base of the penis and removed every 15–30 minutes alone or combined with needlepoint spot and bipolar electrocoagulation control is effective. We try to avoid the use of electrocautery to minimize the potential for tissue injury and inject 1:100 000 epinephrine in 1% lidocaine along the proposed incision line and in the glans deep to the urethral plate. In our experience, this injection affords the twin benefits of adequate local hemostasis while hydrodissecting a reliable plane between the skin and dartos fascia.

Dressing and urinary diversion

An ideal post-hypospadias repair dressing should provide adequate but pliable compression and be easily removable within 48 hours in most cases. Numerous variations in type and style of dressing have been proposed, whereas even no dressing at all is a viable alternative for some.[73,74] We continue to prefer the 'sandwich-type' dressing preferred by Duckett that compresses the penis against the lower abdominal wall by placing a Telfa pad and a folded gauze sponge on top of the penis followed by a bio-occlusive dressing (Tegaderm).

Most surgeons prefer urinary drainage with a catheter following proximal and midshaft hypospadias repairs, yet no study has proven its utility in distal repairs. A multicenter experience reported by Hakim et al revealed similar results for distal repairs with or without postoperative urethral diversion.[75] We use a 6 Fr hydrophilic Kendall catheter placed through the neourethra and sutured to the glans with a Prolene suture anchored to the inner aspect of the meatus to avoid scarring of the glans. Because the rate of urinary infection is no different between an open and closed system, we allow the open end of the Kendall tube to passively drain into the diaper and prescribe prophylactic antimicrobials.[76] This approach helps prevent inadvertent catheter removal and eliminates 'air-lock' in the drainage tubing.

Correction of penile curvature

Preoperative assessment probably overestimates the incidence of ventral curvature associated with hypospadias, especially in distal cases. After the penis is degloved, we have found bending in only 10% of distal hypospadias, but over 50% when the meatus is midshaft or more proximal. Most often, curvature is less than 30° in distal cases, but can be greater than 45° in some proximal hypospadias. The observation in some cases that degloving corrects apparent bending and reveals a deficiency of ventral shaft skin indicates that skin disproportion is one etiology of curvature. Similarly, based upon clinical experience, bending of the penis can also result from shortening

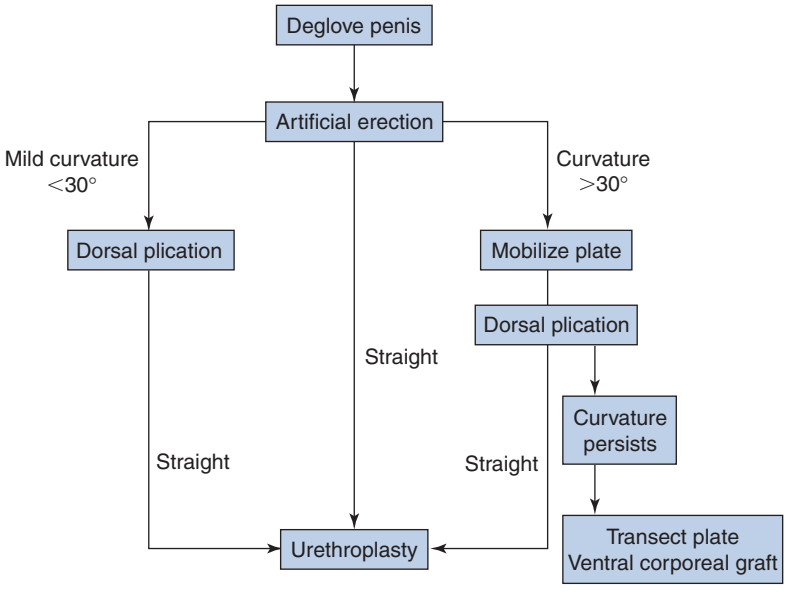

Figure 71.7 Algorithm for penile straightening. Most ventral curvature will be corrected by degloving the penile shaft. Minor residual bending is straightened by dorsal plication. Severe curvature is much less commonly encountered, but may require transection of the urethral plate and ventral corpora cavernosal grafting for satisfactory correction.

or inelasticity of the corpus spongiosum splayed to either side of the urethral plate, shortening or inelasticity of the plate itself, and/or disproportionate development of the ventral vs dorsal corpora cavernosa surfaces.

Because degloving alone can decrease or resolve bending, it is reasonable to preserve the urethral plate in all cases until the extent and etiology of curvature is clear. Artificial erection is performed by normal saline injection into the corpora using a 25-gauge butterfly needle. One algorithm for management of persistent curvature is shown in Figure 71.7. Minor bending <30° is corrected by dorsal plication in the midline, as advised by Baskin et al,[28] to avoid injury to the neurovascular bundles (Figure 71.8). The region opposite the point of curvature is determined and Buck's fascia incised. A single 6–0 PDS suture is placed into the intercorporeal septum and tied, burying the knot. Repeat erection confirms straightening.

Additional plication stitches can be placed when bending exceeds 30°; however, we prefer alternative measures since multiple dorsal stitches could shorten the penis. In this situation, we mobilize the splayed corpus spongiosum off the underlying corpora cavernosa from the normal urethra proximally to its insertion in the glans wings distally. We repeat the artificial erection and we straighten any residual minor bending by dorsal plication. If more severe curvature persists, dissection continues under the urethral plate, releasing all remaining attachments to the corpora. If repeat erection still demonstrates more than 30° of curvature, we transect the urethral plate proximally at

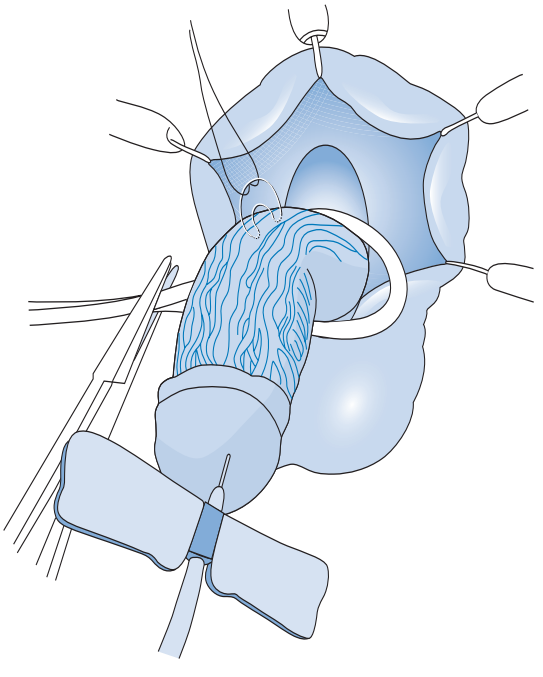

Figure 71.8 Dorsal plication for penile straightening. Buck's fascia is incised in the midline opposite the region of maximum curvature. A 6–0 PDS suture is placed as shown. Repeat erections should confirm absence of curvature.

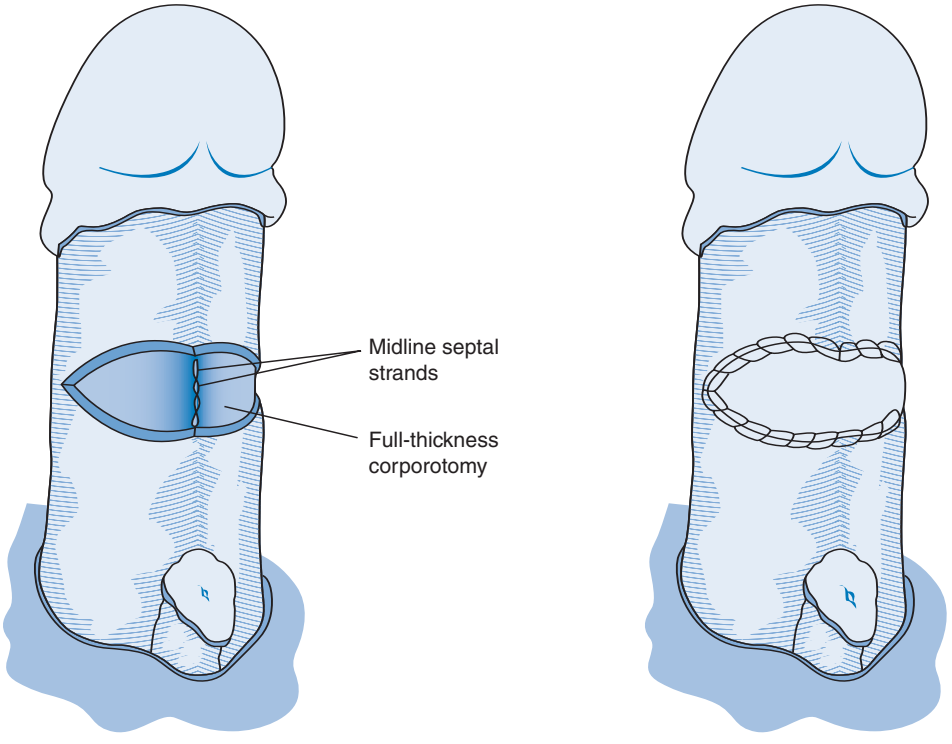

Figure 71.9 Incisional grafting of the ventral corpora cavernosa for penile straightening. A transverse incision is made through the tunica albuginea from approximately the 3 to the 9 o'clock position at the point of bending. The underlying spongy tissue is not disturbed. The graft is then secured around the perimeter of the wound, lengthening the ventral corporeal surface.

its junction with the normal urethra or dissect the urethral plate back and replace the urethra with a graft (two stages) or with a flap (one or two stages).

Curvature requiring transection of the urethral plate is encountered in less than 5% of cases.[77] In some, release of a short, inelastic plate either straightens the penis or reduces curvature so that dorsal plication is possible. In others, significant corporeal disproportion results in persistent curvature that requires ventral lengthening, especially when the phallus is already short. In this case, we make multiple superficial transverse incisions along the corpora cavernosa until the penis is straight. Alternatively, a single incision is made through the tunica albuginea at the point of maximal bending from the 3 to 9 o'clock position and the resultant defect grafted using dermis,[78–80] tunica vaginalis,[81,82] or single-ply small intestinal submucosa (SIS)[83,84] (Figure 71.9).

Urethroplasty

There have always been multiple options for urethroplasty. We present our two approaches regarding the best method for hypospadias repair.

Distal hypospadias

WTS [first author]: No single repair can address the entire spectrum of hypospadias, and surgeons have traditionally categorized options for urethroplasty into those for distal vs proximal defects. For clarity, we maintain the practice of considering distal and proximal techniques. However, I believe this distinction is no longer valid, and that it is better to instead classify hypospadias into those situations where the urethral plate can be tubularized and those where it cannot.

In a recent review of 106 consecutive patients with hypospadias,[77] we found the urethral plate could be tubularized in 102 (96%), including all with distal hypospadias. Ventral curvature was noted in 24 (23%), but was less than 30° in 17 patients and therefore corrected with a single dorsal plication. In another four cases, we elevated the splayed corpus spongiosum from the corpora in conjunction with dorsal plication, which enabled us to preserve and tubularize the urethral plate. The remaining three patients underwent transection of the plate, ventral dermal grafting of the corpora, and a staged urethroplasty.

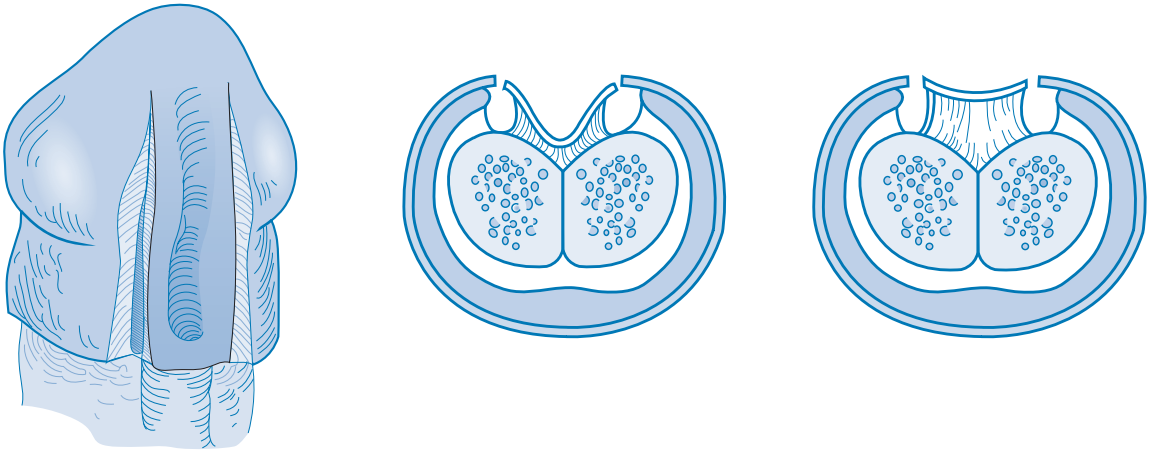

Figure 71.10 Urethral plate incision. The depth of incision varies according to the configuration of the urethral plate. A deep incision is needed when the plate is flat, whereas a deeply grooved plate may already extend to the underlying corpora cavernosal surface.

It continues to be my experience that distal hypospadias can be repaired by urethral plate tubularization, and in the past 5 years no other technique has been used for these cases regardless of whether the plate was flat, clefted, or deeply grooved.[85] Only the depth of midline incision varies according to the anatomy of the plate, i.e. it is deeper when the plate is flat, whereas a relaxing incision may not be needed for a plate that already extends to near the corpora (Figure 71.10).

The important steps of tubularized incised plate (TIP) urethroplasty for distal hypospadias are illustrated in Figure 71.11. A 5–0 polypropylene suture is placed into the glans for traction. Later, this suture is used to secure the urethral stent. The initial skin incision depends upon whether the family prefers circumcision or foreskin reconstruction. When circumcision is desired, care is taken to preserve sufficient inner prepuce so that a so-called 'mucosal collar' can be approximated in the ventral midline after glan-

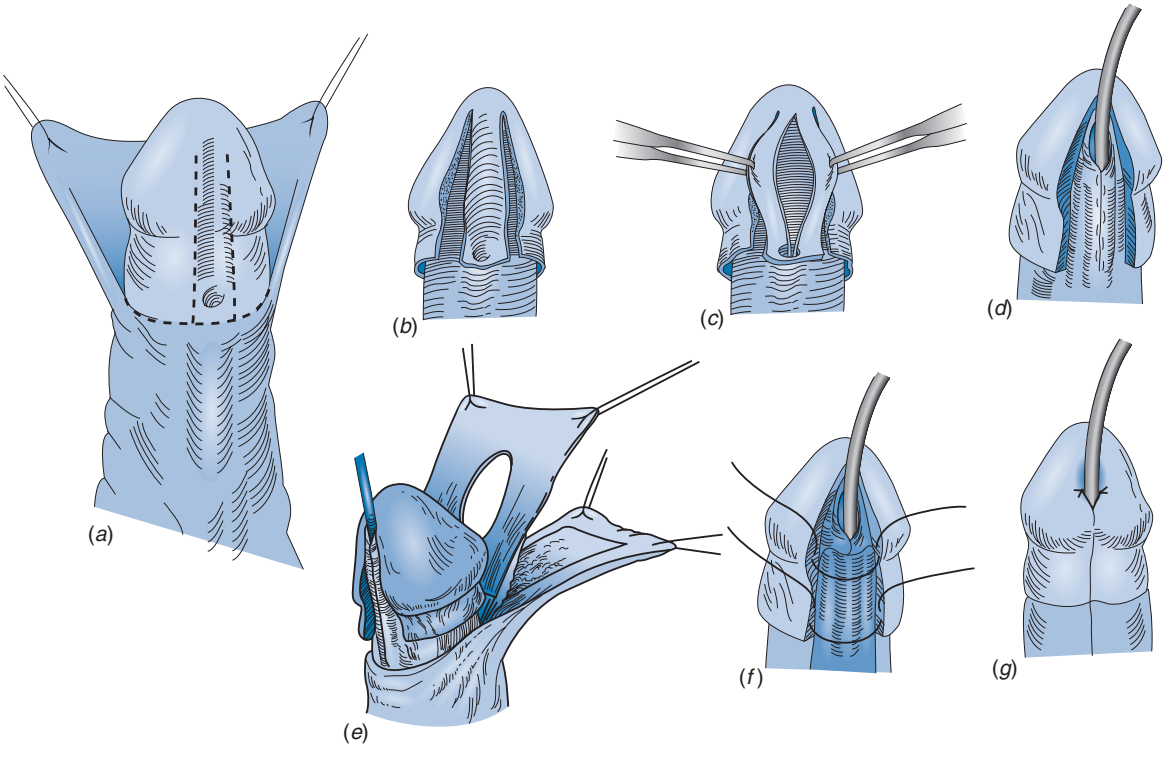

Figure 71.11 Tubularized incised plate (TIP) urethroplasty.

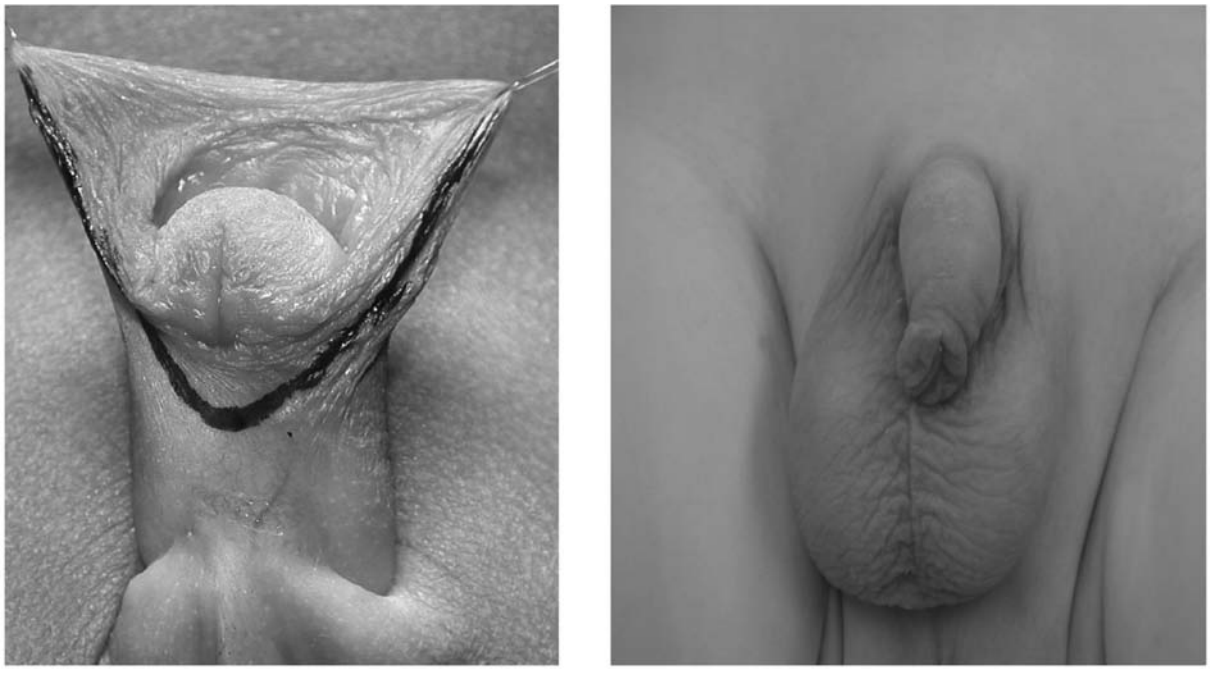

Figure 71.12 Skin incision for foreskin-preserving hypospadias repair. Stay sutures are placed in the corners of the prepuce at the junction of the inner and outer surfaces. Then a V-shaped incision is made to a point 2 mm proximal to the meatus. The penis is degloved ventrally to normal dartos tissues. During skin closure after urethroplasty the inner layer, intervening dartos, and outer layers are separately approximated.

uloplasty.[86] We then deglove the penis to the penoscrotal junction. We next perform an artificial erection and correct the penile curvature. If we plan to reconstruct the foreskin, the skin incision extends from the corners of the dorsal preputial hood to 2 mm proximal to the meatus (Figure 71.12). We then release the ventral shaft skin until we encounter normal dartos tissues.

Next, the junction of the glans and urethral plate is marked and these lines for incision are infiltrated with 1:100 000 epinephrine or, alternatively, a tourniquet is used around the base of the penis for hemostasis. We then develop glans wings in the plane along the surface of the corpora and dissect laterally to lift the spongiosum tissue off of the corpora to provide a tension-free approximation of the glans after reconstruction of the urethra.

The key step in the procedure is midline incision of the urethral plate. Countertraction maintained by the surgeon and assistant along the margins of the urethral plate facilitates this maneuver, as the surgeon makes the relaxing incision from within the meatus to the distal extent of the plate, taking care not to continue the incision into the glans apex. The relaxing incision carries deeply to near the underlying corporeal surface.

A 6 Fr Silastic stent is passed into the bladder and secured to the glans traction suture. The urethral plate is tubularized, beginning at the neomeatus, and using 7–0 polyglactin suture. The first stitch is placed through the epithelium at a point just distal to the middle of the glans, so that the meatus has an oval, not rounded, configuration. The tubularization is completed with a running two-layer subepithelial closure, turning all epithelium into the neourethra lumen.

We raise a dartos pedicle flap from the preputial hood and dorsal shaft skin in patients undergoing circumcision, then buttonhole and transpose the flap ventrally to cover the entire neourethra. When we reconstruct the foreskin, this layer is not accessible.

Glanuloplasty is an important determinant of the final cosmetic outcome. A 7–0 polyglactin suture is placed through the epithelium at the desired point for the ventral lip of the meatus. A second subepithelial 7–0 stitch is placed in this same location to further buttress the neomeatus and reduce the likelihood that partial dehiscence will result in a larger than normal opening. It is not necessary to secure the glans to the underlying neourethra. The remainder of glans approximation is then done in a single layer using interrupted 6–0 polyglactin subepithelial sutures proximal to the corona.

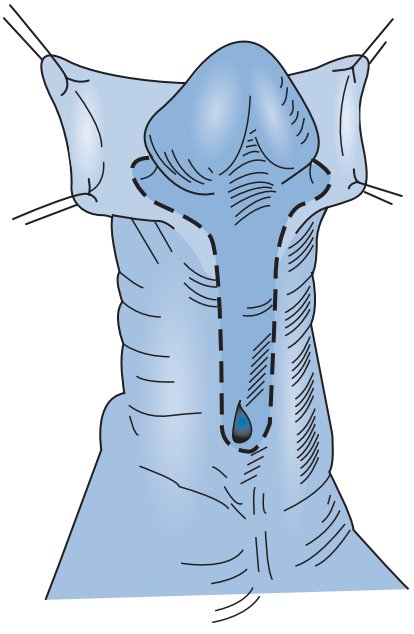

Figure 71.13 Proximal tubularized incised plate (TIP) urethroplasty.

The shaft skin is closed with subepithelial 7–0 polyglactin stitches to minimize risk for suture sinuses. During circumcision, the dorsal hood is incised on the midline to the level of the subcoronal collar of the inner prepuce. We suture this point, and then approximate the ventral shaft skin up the midline, simulating the normal median raphe. Next, we excise the excess skin and suture the remaining edges. When we plan to reconstruct the foreskin, we first close the inner prepuce with interrupted stitches, then approximate the subcutaneous dartos, and finally sew the outer shaft skin, giving a three-layer closure. We apply a Tegaderm dressing and leave the stent open dripping into diapers for 1 week.

Proximal urethroplasty

We make a U-shaped incision immediately adjacent to the urethral plate to minimize risk of incorporating hair follicles into the neourethra (Figure 71.13). While we accomplish foreskin reconstruction in some proximal cases, the high incidence of ventral curvature limits this option.

After degloving, we dissect the urethral plate along the lateral edges of the corpus spongiosum off the underlying corpora cavernosa. We later approximate lateral strips of spongy tissue later over the neourethra as a barrier layer;[87] mobilization sometimes also lessens the extent of penile bending. Then we perform artificial erection and straighten the curvature as needed.

We make a midline incision of the urethral plate to assess the 'health' of this tissue. If the plate appears to lack supple subepithelial tissue, it is resected and not used for urethroplasty (Figure 71.14). The glans is left undisturbed until this point. When the incised plate is satisfactory, we dissect the glans wings from the urethral plate, as described for distal repairs. We

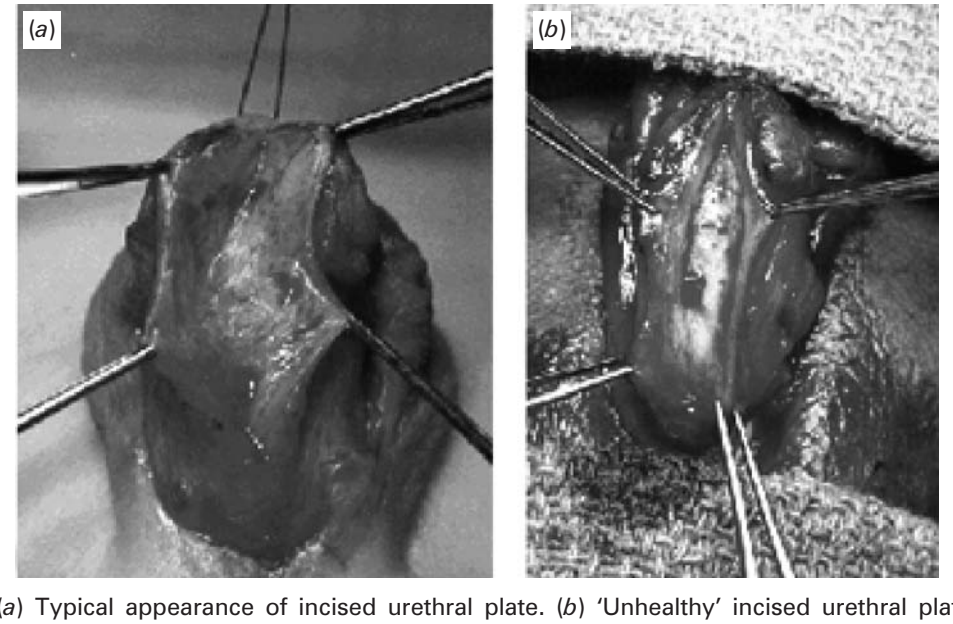

Figure 71.14 (*a*) Typical appearance of incised urethral plate. (*b*) 'Unhealthy' incised urethral plate. Rarely, the incised urethral plate in proximal hypospadias appears deficient in subcutaneous connective tissues and may seem less elastic when handled with forceps. In the authors' experience, tubularization of a plate with this gross appearance has resulted in wound dehiscence or neourethral contracture with recurrent curvature.

then incise the plate in the midline in preparation for tubularization. We then pass a 6 Fr stent into the bladder. Sometimes, there may be difficulty negotiating the catheter past an enlarged utricle. In these cases we pass a 7 Fr cystoscope under vision into the bladder and place a wire over which the stent can be maneuvered.

To create the longer neourethra in proximal repairs, a two-layer, 7–0 polyglactin subepithelial closure is preferred, the first using interrupted stitches and the second, a running stitch. We take care to turn all visible epithelium into the neourethral lumen. We then close the previously mobilized corpus spongiosum, followed by coverage of the entire repair by a dartos pedicle flap. Glanuloplasty follows and then skin closure. We then correct significant penoscrotal transposition at this point. Finally, a Tegaderm dressing is applied. The stent diverts urine for 10 days.

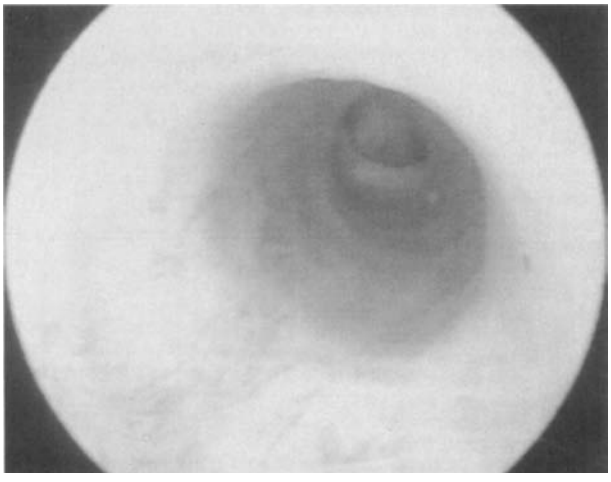

Figure 71.15 A healed neourethra after TIP repair. Note the absence of visible scarring from the midline urethral plate incision.

Results

Advantages of TIP hypospadias repair include urethroplasty without skin flaps and reliable creation of a vertical, slit neomeatus giving a normal cosmetic appearance. The ability to tubularize the urethral plate without incorporating additional skin not only simplifies the operative procedure but also increases its versatility. Consequently, TIP can be used for primary surgery, after circumcision, and for reoperations as discussed below. A deeply grooved urethral plate is needed to achieve a vertical meatus. Midline TIP incision converts a flat or slightly clefted plate to this desired configuration.

Initially, after we introduced the technique, there were concerns that the dorsal defect resulting from plate incision would heal with stricture or meatal stenosis. However, a study of 21 patients undergoing urethral calibration 17–84 months (mean 36 months) postoperatively found no stenosis or stricture.[88] Subsequently, it was reported that complications increased if the plate measured <8 mm or was flat before incision.[89] We reviewed outcomes in 159 consecutive boys undergoing TIP and found no relationship between plate characteristics before incision and final outcomes.[90,91] Stenosis noted when the urethral plate is narrow or flat emphasizes the important role of deep midline incision, which we make to the level of just superficial to the corpora.

Meatal stenosis after TIP can also result from tubularizing the plate too far distally. I prefer to begin tubularization at the neomeatus just beyond the midglans, creating an oval, not rounded, opening. The 3% cumulative incidence of meatal stenosis from a total of 779 patients in 15 published series suggests this complication more likely indicates technical problems than an inherent tendency for the incised plate to scar.[92] Similarly, in this review there were no cases of urethral stricture. Instead, urethroscopy as long as 7 years after TIP repair demonstrates no visible scarring and a normal-appearing neourethra (Figure 71.15).

Despite routine use of a dartos flap to cover the neourethra in both distal and proximal TIP repairs, fistulas remain a potential complication. Initially I closed the neourethra with interrupted stitches placed through the epithelium of the plate, noting a 4% fistula rate. Subsequently, we have used a running subepithelial closure of the plate, and the incidence of fistulas has diminished to 0.5% in distal repairs. Similarly, we tubularized proximal neourethras with stitches through the epithelium and then covered with dartos flaps, and fistulas occurred in 21% of cases.[93] Following this experience, we changed the closure to include subepithelial sutures. The corpus spongiosum, when available, was approximated over the neourethra in addition to the dartos flap, with the rate of fistulas diminishing to 10% following this modification. Another series of 100 proximal TIP repairs with subepithelial tubularization and a dartos barrier flap found that only 3% of patients developed fistulas.[94] The importance of a barrier flap in reoperations has been emphasized by two reports in which fistulas most often occurred when a flap was not used.[90,91]

Although essentially all distal repairs can be accomplished by tubularization of the urethral plate, I have encountered a few cases in which the incised plate

overlying the penile shaft in proximal hypospadias did not appear suitable for urethroplasty (see Figure 71.14). In two boys, I performed TIP nevertheless, with one wound dehiscence and one contracture of the neourethra resulting in curvature. In this circumstance, there appears to be a paucity of subepithelial tissues and perceived rigidity to the plate. In subsequent patients with this finding, the plate has been excised and a staged urethroplasty performed.[77]

Staged urethroplasty

There are two situations in which the urethral plate cannot be tubularized: most common is penile curvature greater than 30°, which leads to plate transection; less often encountered is an 'unhealthy' incised plate. Options for repair include tubularized preputial flaps or staged urethroplasty, which traditionally has been done using skin flaps from the dorsal prepuce transposed ventrally. However, I now favor use of a buccal graft quilted onto the corpora to create a neourethral plate for tubularization at the second operation. This graft can be placed directly over transverse incisions made into the corpora for straightening. Staged buccal grafts have reliably taken and have not been reported to develop diverticula.

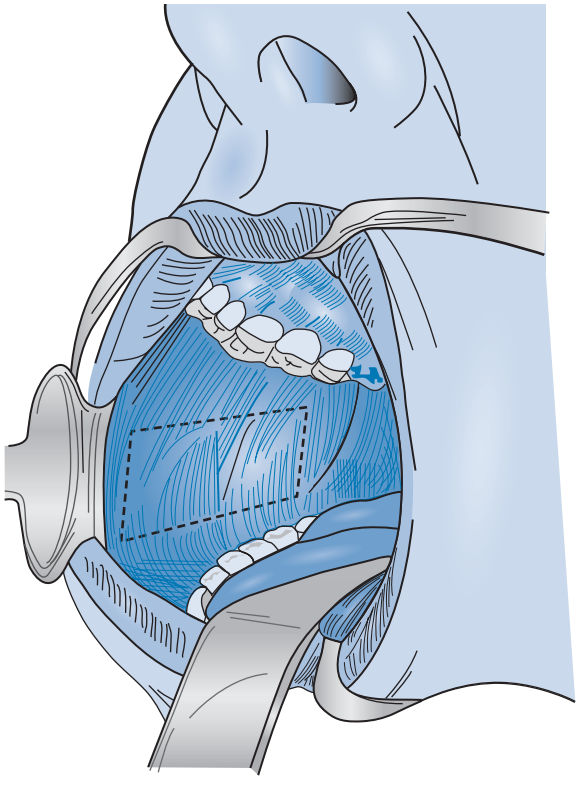

Figure 71.16 Harvesting the buccal mucosa graft for urethroplasty.

Either inner lip or cheek can be used to obtain buccal epithelium, but I prefer to use the thinner lip tissue for grafting in the glans and thicker cheek for the penile shaft. The proposed site is outlined slightly larger than needed and infiltrated with 1:100 000 epinephrine, taking care to identify and avoid injury to the parotid duct near the upper second molar (Figure 71.16). A first-generation cephalosporin is given, along with glycopyrrolate to diminish oral secretions during harvest. Dissection seeks to minimize fat and muscle on the underside of the graft. The donor site is packed until bleeding stops and then coated with fibrin glue for coverage. The cheek or lip wound is not closed. Meanwhile, the graft is further defatted, as shown in Figure 71.17.

We next secure the graft with interrupted polyglactin stitches around the perimeter of the wound and then quilt it into place with additional absorbable sutures 0.5 cm apart down the midline and then to either side between the perimeter and midline stitches. This quilting minimizes the likelihood that hematoma will collect under the graft and prevent revascularization. We leave a 'tie-over' dressing of Vaseline gauze to secure the graft further. We leave this dressing postoperatively with a catheter for urinary diversion for 7–10 days.

In primary repairs, we use the graft to bridge the gap between the proximal urethrostomy and the preserved urethral plate in the glans. We leave the distal aspect of the plate undisturbed until the second stage, or tubularize it at the first stage with the buccal graft interposed between proximal and distal urethros-

Figure 71.17 Defatting the graft. Although pin boards can be used, the authors find it simpler to defat the graft as shown. Tactile sensation helps determine the depth of excision and avoid inadvertent epithelial holes.

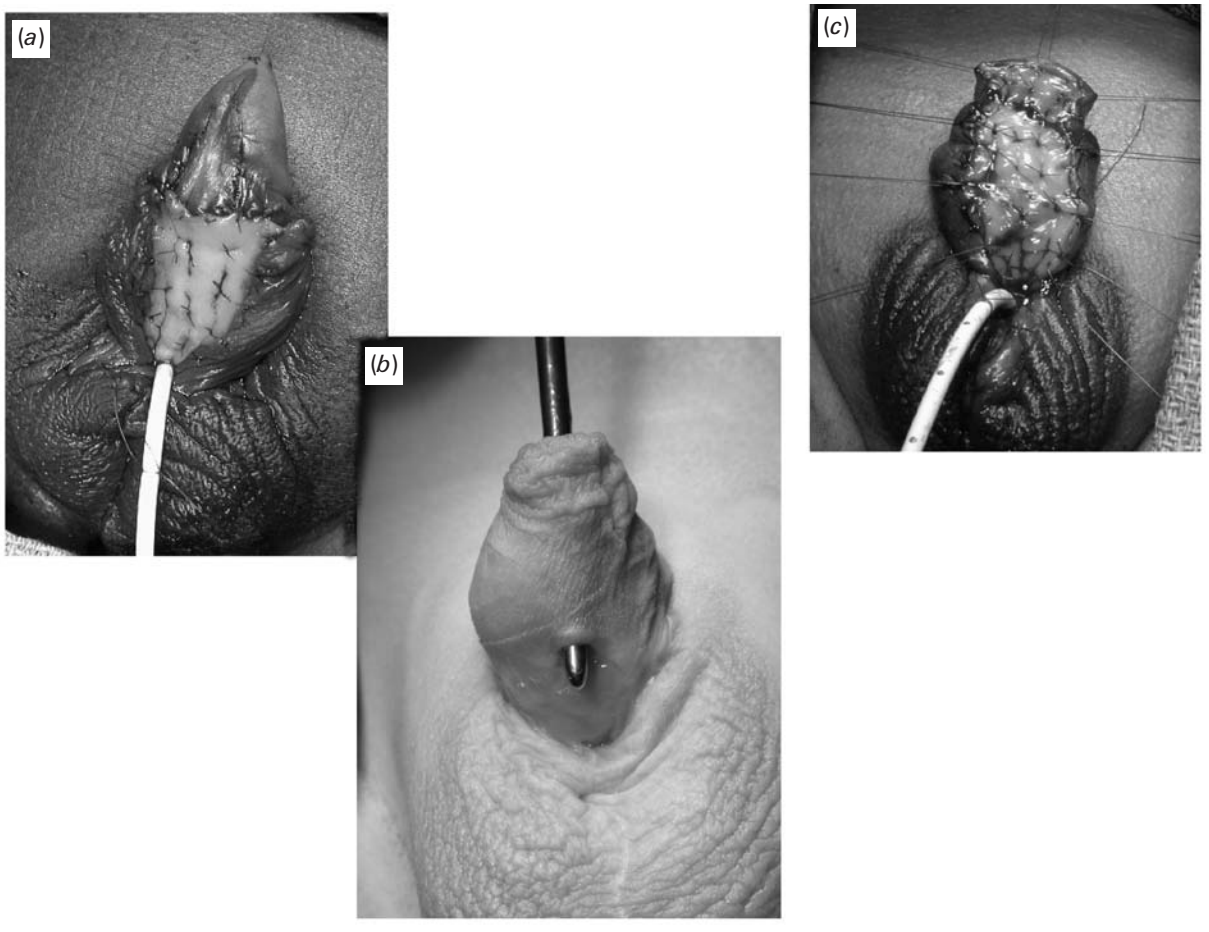

Figure 71.18 Options for buccal grafting in primary hypospadias repair when the urethral plate cannot be used. (*a*) The graft is interposed between the proximal urethrostomy and the distal intact glanular urethral plate. (*b*) The graft from the proximal urethrostomy to the distal tubularized urethral plate. (*c*) The graft from the proximal urethrostomy to the tip of the glans.

tomies. Alternatively, we resect the glanular plate and extend the graft to the tip of the glans (Figure 71.18).

The graft take is visually apparent. The second-stage tubularization of the now-vascularized 'neourethral plate' is done 6 months later using a two-layer closure turning epithelium into the lumen. We cover the neourethra with a dartos flap, or a tunical vaginalis flap if there is not sufficient dartos available. A catheter provides urinary diversion for 7–10 days.

DAC [third author]: The goals of hypospadias repair are to provide a straight penis adequate for sexual function and to move the urethral meatus to the tip of the penis to allow the boy to void with a normal urinary stream.

The glans size, the degree of chordee, the meatal location, and the quality of the foreskin all influence the choice of repair. Surgeons have developed a myriad of hypospadias techniques. My training, the interpretations of the ample body of hypospadias literature, and my clinical experience as tempered by the suggestions of my colleagues have all influenced my choice of procedure for the individual boy. Early in my career, meatal-based urethral flaps and staged repairs were frequent. At the CHOP, which has historically relied on single-stage transverse preputial island flaps and tubes, I began to do more of these and fewer staged repairs.

To avoid the creation of a 'hypospadias cripple', a skilled team with considerable experience must perform the reconstruction. The surgeon should not enter the operating room with an unyielding plan. They should have an abundance of techniques available and a broad fundamental knowledge in the principles required for a successful outcome.

I believe that the reliability of the repair is reduced when the perfusion of the tissue is at risk. I also believe that the repair is jeopardized when tissues are introduced in the repair that are foreign to the urethra.

Since adequate urethral tissue is rarely present in the boy who has had multiple hypospadias repairs, the advantages vs the disadvantages of each technique must be weighed. A preputial flap, for example, introduces well-perfused foreign tissue to the urethra at the expense of a higher risk of diverticulum. On the other hand, the TIP or Snodgrass repair employs local urethral tissue in the reconstruction, which perhaps is less well supplied with blood. To compensate, additional dartos tissue should be moved to cover the repair. Because of the interest in island flaps at our institution, most of our experience with primary repair for hypospadias has been using either an island onlay (the vast majority) or an island tube (less commonly). After our experience broadened with the onlay, we used it even in cases where there was considerable chordee.[95] I am now more cautious with this. In at least one case, after plicating the dorsum of the penis, I have put the penis on compression and therefore shortened it to a degree. For this reason, in boys with considerable chordee and proximal hypospadias, I now rely more on the island tube. I am less resistant to transecting the urethral plate, particularly since having enjoyed improved results with a modification of the island tube.[96] In addition, I have found that what frequently begins as a two-stage repair, in my hands, often results in three stages.[97]

Over time, we have modified both the island onlay and the transverse preputial island flap and now operate on younger children. Studies by some of the best surgeons have shown that adult hypospadias repair is far less successful than repair in younger children.[98] Tissue factors that contribute to near scarless wound healing in the fetus[99] are less likely to be present in the older boy and the adult.

What follows is a description of the major repairs we use at CHOP, in addition to the TIP described above.

Meatal advancement and glanuloplasty

The MAGPI offers reliable cosmesis and long-term success when applied to glanular and selected coronal meatus repairs. Recently, we have used this repair less commonly and will usually opt for a TIP repair in cases where we would have used the MAGPI in the past. Presence of urethral mobility and a rounded glans, along with the absence of significant chordee, should be assessed to ensure an ideal outcome and avoid meatal regression. We assess urethral mobility by distal traction on the meatus with fine forceps.

The MAGPI begins with a circumferential incision 6–8 mm proximal to the corona of the glans and proximal to the meatus (Figure 71.19a). We dissect the penile shaft skin with extreme care ventrally over the corpus spongiosum to avoid urethral injury. A longitudinal incision from the dorsal distal edge of the meatus is carried to the distal glans groove as it transects the transverse bridge of tissue that is often present (Figure 72.19b). We approximate the incised

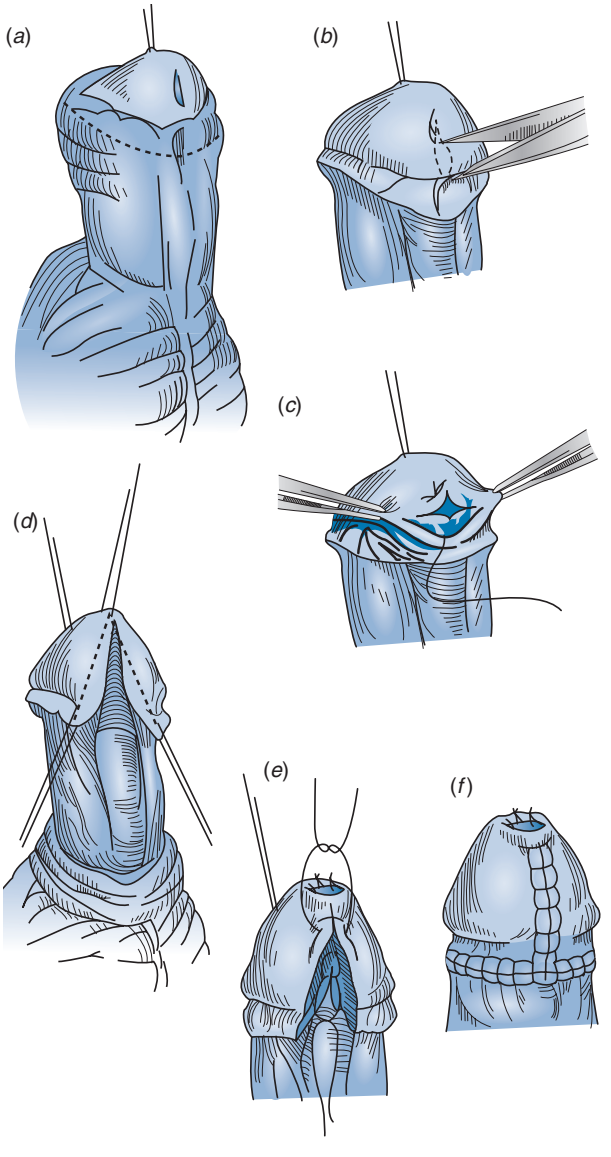

Figure 71.19 Meatoplasty and glanuloplasty repair (MAGPI). (*a*) A circumferential incision 5 cm below the corona. (*b*) The transverse bridge of the tissue distal to the meatus is sharply incised. (*c*) A Heineke–Mikulicz closure opens and advances the meatus. (*d*) The ventral meatal edge is pulled distally and the exposed glans edges are trimmed and approximated. (*e*) Glanuloplasty is performed with subepithelial sutures to leave a rounded, conical glans. (*f*) The dorsal skin is transferred ventrally, excess skin is excised, and no catheter is left in place.

tissue edges in a Heineke–Mikulicz fashion with 7–0 absorbable suture to advance the meatus distally (Figure 72.19c). We pull the medial edge of the ventral meatus distally and the exposed glans edges are trimmed to leave the glans with a cosmetically sound, rounded appearance (Figure 72.19d). The dorsal hooded foreskin is trimmed in the midline to allow adequate ventral skin transfer, and skin is approximated to the glans with absorbable, subcuticular suture to complete the repair (Figures 72.19e,f).

In cases where the urethral meatus is proximal to the corona or if the ventral penile shaft skin is thin, we are less apt to use the TIP repair and tend to use the onlay island flap repair.

Onlay island flap

Numerous alternatives for single-stage neourethral reconstruction for proximal hypospadias, ranging from prepuce-based flaps, the incised plate urethroplasty to free grafts, have been described with varying results.[93,100–102] Whereas surgical innovation has enabled most variants of hypospadias to be repaired with preservation of the urethral plate, proximal hypospadias with severe chordee may still require transection of the urethral plate. From the time Duckett first described the transverse preputial island flap (TPIF) repair in 1980,[65] we have continued to prefer the incorporation of vascularized preputial flaps for these difficult cases.

To ensure hemostasis, we infiltrate a solution of 1:100 000 epinephrine and 1% lidocaine along the marked line. We then incise the skin and deglove the penis to Buck's fascia, beginning the dissection ventrally – from the urethral meatus to the penoscrotal junction – and then dorsally to the penopubic junction. We then incise the urethral meatus proximally until we see normal-appearing vascularized corpora spongiosum and normal bleeding from the native urethra. We then perform an artificial erection with injection of normal saline. If the penis is curved less than 30°, we plicate the dorsum of the penis with a pair of vertical incisions closed horizontally.

Van Hook first introduced the concept of a preputial flap based on a vascular pedicle to repair proximal hypospadias in 1896.[1] Asopa and colleagues developed the effective use of inner preputial skin for a substitution urethroplasty and Duckett furthered this technique by describing a TPIF repair in 1980.[65,103] The island onlay flap evolved from the TPIF as experience demonstrated that repair of the chordee with hypospadias can be accomplished by dissection of the subcutaneous tissue and dorsal midline plication, and that division of the urethral plate is required in only 10% of cases.[52] The concept that spongiosum consists of vascularized tissue and smooth muscle bundles that may be utilized in a hypospadias repair evolved over the 1980s after histologic examination.[104,105] We use the onlay island flap for more than 90% of our patients with subcoronal hypospadias.

The circumferential incision begins dorsally, 6–8 mm proximal to the corona, and extends ventrally just proximal to the meatus (Figure 71.20a). We then

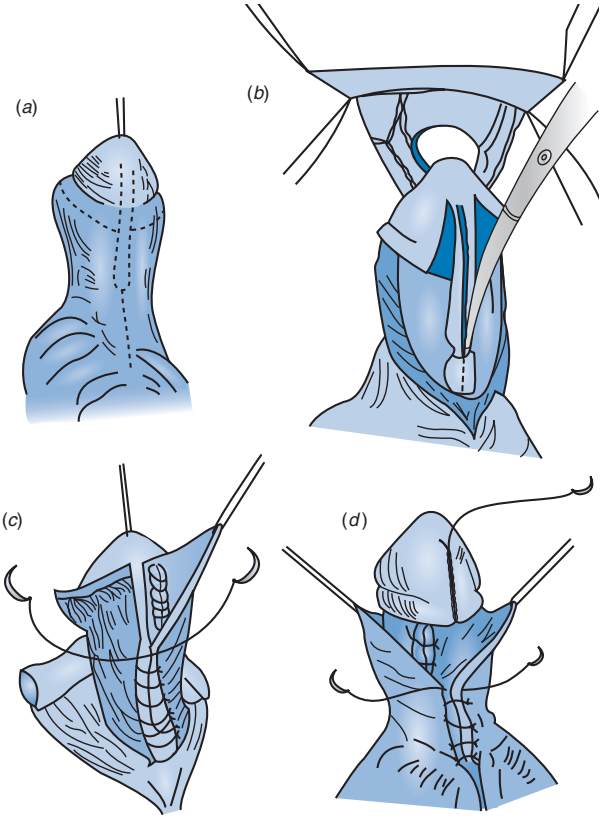

Figure 71.20 Onlay island flap. (*a*) Dashed lines indicate the initial circumcising incision carried along to the ventrum and anteriorly to provide a subcoronal collar. Note the midline incision is carried to the penoscrotal junction to facilitate adequate inspection of spongiosal tissue. (*b*) The penis is degloved and the native urethral meatus is incised back to normal spongiosal tissue. Thin gossamer-like dysplastic urethral tissue is incised until normal, well-vascularized tissue is seen. Stay sutures separate the inner and outer faces of the preputial flap and the onlay flap is mobilized with mesentery intact. A buttonhole in the mesentery allows ventral transposition without increasing torque on the penis. (*c*) The edges of the flap are sutured with subepithelial interrupted sutures. Tailoring of the flap minimizes the risk of diverticulum formation. (*d*) Byars flaps cover the skin-deficient ventrum with subcuticular sutures.

extend the incision further proximally to split ventral shaft skin in the midline to the penoscrotal junction (Figure 71.20b). We make parallel incisions 5 mm wide or narrower along the urethral plate distally to the glans tip at a point where the flat ventral surface of the glans begins to curve around the meatal groove. We take care to keep these incisions superficial to avoid injury to underlying spongiosum. Dissection of the skin should avoid entering a plane into the intrinsic vascularity of the skin to preserve its viability as a preputial flap. As is commonly the case, if dissection of the penile ventrum reveals thinned spongiosal tissue that is nearly transparent, we incise the urethra proximally to what appears to be normal spongiosum. The urethral plate need not be more than 2 mm wide prior to the onlay transfer.

Then we outline the flap on the inner preputial skin surface with interrupted 5–0 polypropylene stay sutures (see Figure 71.20b). We place the sutures to accentuate the fold of tissue between the inner and outer prepuce. The initial incision just beneath the skin at the junction between the inner and outer preputial faces of foreskin sharply divides an 8–10 mm segment of this epithelium. We are careful to harvest the flap following a midline incision on the ventral shaft to the penoscrotal junction, allowing flattening of the shaft skin that facilitates the establishment of the plane between the blood supply to the flap and the blood supply to the penile shaft skin.

The dissection of the vascular pedicle begins at the mid-shaft where we have an easier time separating it from the blood supply to the dorsal penile shaft skin. This approach to the harvest of the flap easily identifies the proper plane and assures preservation of blood supply to the flap. The splitting of ventral shaft skin, completed during the initial circumcising skin incision, releases the base of the dorsal vascular pedicle and allows for wider mobilization of the preputial foreskin for flap isolation. The flap is then rotated ventrally, or more commonly, transferred by creating a window in the vascular mesentery through which the glans is passed, and then tapered proximally and distally (Figure 71.20c). To avoid turbulent voiding that may contribute to fistula formation and diverticulum, we aggressively trim the proximal flap to a wedge shape to provide a consistent caliber of the tube as the neourethra meets the spatulated native urethra. The combined width of the preserved plate and the flap should be about 10 mm and no wider at the anastomosis than at the urethral meatus.

Experience has shown that too wide a neourethra may lead to kinking or diverticulum formation. The appropriately designed flap is then sutured into place using lubricated interrupted 7–0 polyglactic suture at the proximal meatus and then in an interrupted subepithelial fashion along the lateral edges of the plate (see Figure 71.20c). We no longer close the flap over a feeding tube. We prefer to place the tube at the conclusion of the construction of the neourethra. The 8 Fr feeding tube then serves as a spacer to assure an adequately sized glanuloplasty. We complete the glanuloplasty with medial rotation of mobilized glans wings with 6–0 Maxon sutures placed parallel to the cut edge of the glans wing, beginning at the urethral meatus (Figure 71.20d). We place a 6 Fr Kendall urethral stent and the dorsal preputial skin is split in the midline and rotated ventrally to afford adequate circumferential skin coverage.

The transverse preputial island flap

The traditional TPIF creates the neourethra by first tubularizing the dorsal preputial tissue into a neourethra and then transferring the tube to the native urethra proximally and to the glans distally. This repair has been associated with a complication rate of up to 32–42% in some reports.[106–108] In our own experience, we encountered postoperative complications, especially urethral diverticula and meatal stenosis, in a minority of infants when the meatal opening or phallic size was small, or when the chordee was severe.

Recently, we developed a modification of the Duckett transverse island tube that uses one side of the island flap to recreate a urethral plate, with the remainder of the flap tailored and rolled to recreate a neourethra. This modification of Duckett's original procedure has made it easier for us to tailor the urethroplasty to create a more consistent neourethra with less risk for diverticulum and stenosis. We believe that reducing the likelihood of leaving redundant tissue in situ minimizes the risk for diverticulum formation, turbulent voiding, and urethrocutaneous fistula. We perform the TPIF by first placing a glans-holding suture. We next outline a circumcising incision and extend the mark on the midline to the penoscrotal junction. Proximal extension of the ventral incision facilitates subsequent harvesting of the onlay flap by allowing the penile shaft skin to flatten, which results in better visibility of the pedicle of the flap and better separation of the pedicle and the dorsal penile shaft skin. To ensure hemostasis, we infiltrate a solution of 1:100 000 epinephrine and 1% lidocaine along the marked line. We then incise the skin and deglove the

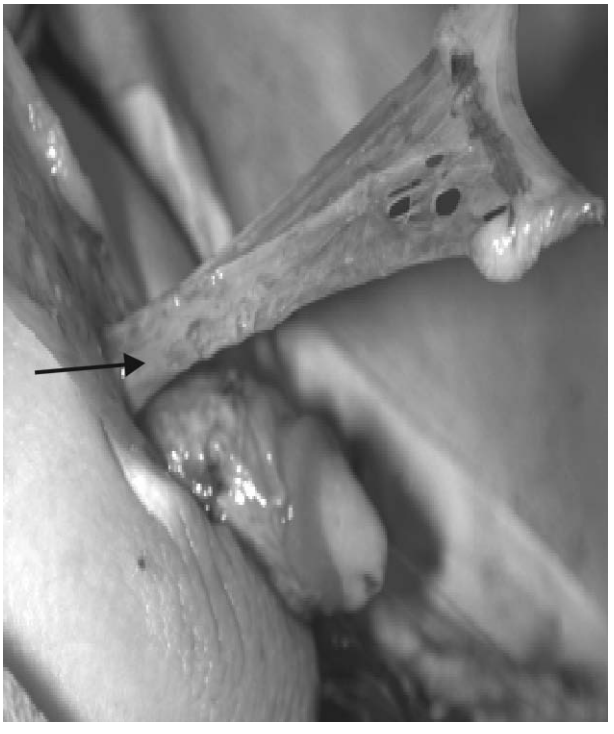

Figure 71.21 An inner preputial skin flap is harvested dorsally. The preputial flap should be harvested beginning at the middle of the penile shaft where the vascular pedicle to the inner prepuce is better defined. The dissection then proceeds proximal to the penopubic junction and distal, completely separating the preputial flap from the distal penile shaft skin. In the past, we rotated the pedicle along one side or the other of the penile shaft. We now create a buttonhole through the vascular pedicle at the penopubic junction, which reduces the extent of the pedicle dissection while minimizing the risk of penile torque after the flap is transferred to the ventrum in preparation for the urethral reconstruction. The arrow indicates the site of the buttonhole for this flap.

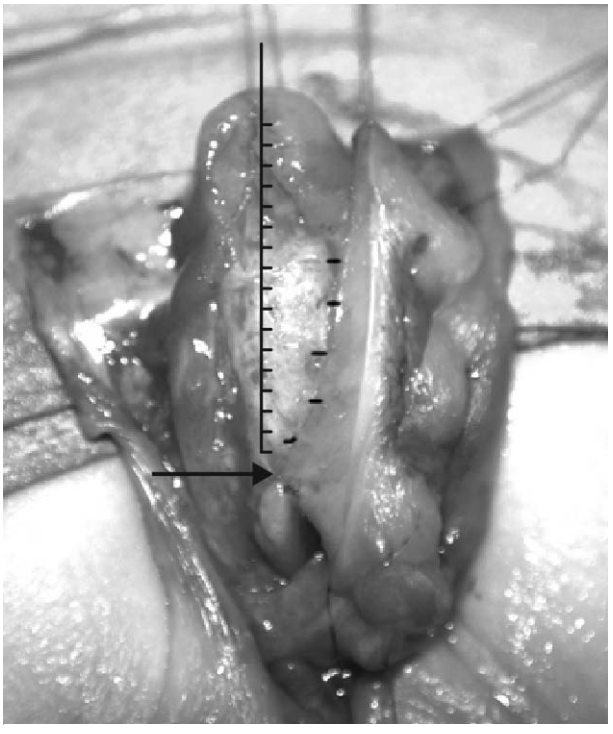

Figure 71.22 The medial margin of the flap is anchored longitudinally to the ventral surface of the corpora cavernosa just to the right or left of the midline using a series of interrupted 7–0 polyglactin sutures. Proposed site of this first suture line is shown by hatched line. These sutures are placed subcuticularly and are not passed through the epithelium of the flap. An arrow indicates the location of the urethral meatus and a vertical solid line represents the proposed plane for placement of a second parallel suture line that completes the tubularization of the neourethra.

penis to Buck's fascia, beginning the dissection ventrally – from the urethral meatus to the penoscrotal junction – and then dorsally to the penopubic junction. We then incise the urethral meatus proximally until we see normal-appearing vascularized corpora spongiosum and normal bleeding from the native urethra. We next perform an artificial erection, and if the chordee is severe, the urethral plate is transected and dissected from the corporeal tissue until the tethering effect of the spongiosum tissue is released. The ventral dissection of the urethral plate sometimes results in a relatively distal urethra displaced to the penoscrotal junction or even to the perineum. We incise the glans deeply in the midline and excess epithelium is trimmed. If required, we make appropriate-length dorsal longitudinal incisions off the midline and close them horizontally to correct chordee. Then we repeat the artificial erection to assure that we have corrected all of the curvature.

When the penis is straight, we harvest the segment of inner prepuce from the redundant dorsal prepuce and buttonhole the mesentery of the flap and transpose the flap to the ventrum (Figure 71.21). We fix the native urethral meatus, which is now in a more proximal location, to the corpora cavernosa with fine absorbable monofilament sutures.

In the past, we constructed the urethra from the island flap by rolling the tissue over a tube and then suturing the proximal end to the native urethral meatus at the penoscrotal junction or at the perineum.[65] We currently modify the construction of the urethra by first anchoring one side of the flap longitudinally to the ventral surface of the corpora cavernosa just to the right or left of the midline using 7–0 polyglactin sutures (Figure 71.22). The anchoring

Figure 71.23 The opposite margin of the flap is stretched to accurately tailor the flap to the desired size of the neourethra (marked area indicates portion of flap to be discarded while preserving underlying vascular supply). The narrowed proximal flap is sutured to the spatulated native urethral meatus.

Figure 71.24 The neourethra is constructed over an 8 Fr feeding tube, which is replaced with a 6 Fr urethral stent prior to application of the dressing.

begins at the posterior wall of the native urethra and proceeds distally to the proposed location of the neomeatus in the glans. This maneuver creates a new urethral plate of inner preputial skin, which no longer binds the ventral corpora. The anchored medial edge of the tube allows the opposite end of the flap to flatten, to facilitate the construction of an appropriately sized neourethra (Figure 71.23). The tube must be narrowed substantially at the proximal anastomosis between the new and spatulated native urethra to align the skin edges and to construct a tube of ideal caliber without a diverticulum at the distal extent of the native urethra. For boys reconstructed in the first year, we use an 8 Fr feeding tube as a template to gauge urethral lumen as the closure proceeds.

To construct the neourethra, we place a second interrupted subcuticular suture line adjacent to the first suture line longitudinally along the ventral penile shaft (Figure 71.24). The urethral reconstruction continues proximally to the glans penis. We complete the glanuloplasty over an 8 Fr urethral stent with 6–0 absorbable monofilament horizontal mattress sutures placed parallel to the cut edge of the glans to cover the distal edge of the tube and to provide an accurate appearance. We exchange the 8 Fr stent for a 6 Fr stent that we leave indwelling for 2–2.5 weeks and a dorsal preputial skin is fashioned to provide adequate skin coverage as in all hypospadias repairs (Figure 71.25).

We cover the repair with a dressing that compresses the penis against the lower abdominal wall by placing a thin non-absorbent pad and a folded gauze sponge on top of the penis followed by a bioocclusive dressing. We use trimethoprim–sulfamethoxazole as antimicrobial prophylaxis while the urethral stent remains – usually for 2–2½ weeks.

The ideal surgical correction for penoscrotal or perineoscrotal hypospadias with severe chordee remains elusive. In addition to allowing a single-stage repair with the attendant benefits to the patient, the primary advantage of the modified TPIF over free graft repairs is the incorporation of vascularized preputial flaps.

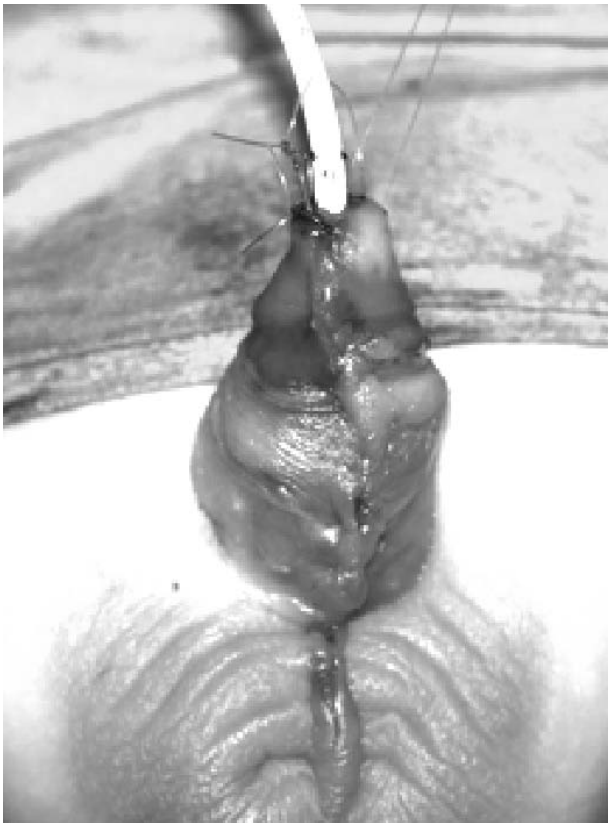

Figure 71.25 The dorsal preputial skin is split in the midline and rotated ventrally to afford adequate circumferential skin coverage with a series of subcuticular sutures.

We recently reported a 20-year review of outcomes utilizing vascularized preputial flaps for severe hypospadias at our institution that confirmed the long-term viability of these flaps.[109] Our preference continues to be to utilize preputial flaps as an island onlay or island tube when the urethral plate is or is not preserved, respectively.[110]

The modified TPIF converts a difficult procedure – the original transverse preputial island tube repair – into a more commonly performed and consistent island onlay repair by recreating a urethral plate with one side of the ventrally transposed inner preputial skin that we anchor to the medial margin of the corpora. By anchoring the medial edge of the flap to the corpora, we can stretch the opposite end of the flap to tailor the neourethra to the size of the native urethra. This minimizes the risk of formation of a urethral diverticulum where the native urethra meets the neourethra, and probably precludes the turbulent voiding that may contribute to formation of urethral diverticula. Furthermore, the adjacent suture lines are dorsal, which may minimize the risk of fistula.

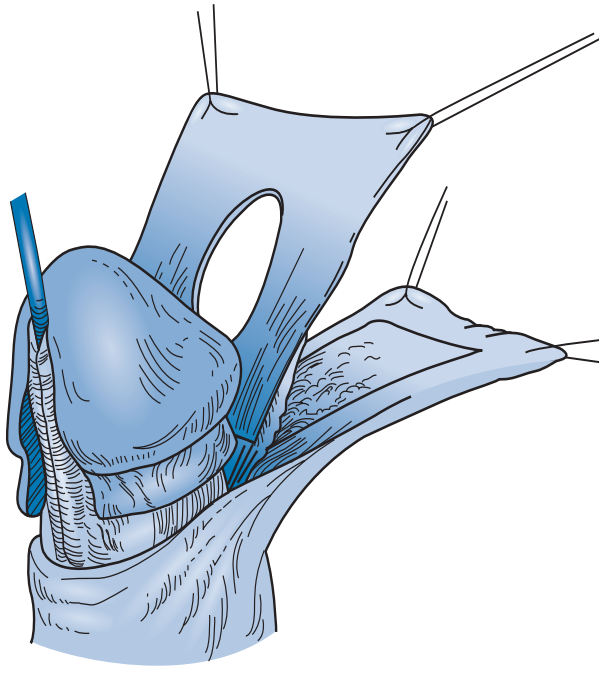

Figure 71.26 Tunica vaginalis flap.

Barrier layers

The most common complication of hypospadias repair is urethrocutaneous fistula. One factor thought to contribute to the development of fistula is overlapping suture lines of the neourethra and overlying shaft skin closure. To prevent fistula, tissue barrier layers are interposed as a preventive measure. In primary repairs, we obtain dartos flaps from the dorsal prepuce and shaft skin and transpose them to the ventrum, either around the side of the penis or via a buttonhole over the glans (Figure 71.26). When we bring these flaps around the penile shaft, proximal dissection extends to the suspensory ligament to avoid penile torsion. We also harvest de-epithelialized dartos flaps from the scrotum. When dartos is not readily available, usually in reoperations, we use tunica vaginalis flaps (Figure 71.27). It is important to dissect these flaps well up the spermatic cord to avoid postoperative traction on the ipsilateral testis, especially during erections.[111]

Skin closures

Hypospadias repair in the United States has traditionally included circumcision to remove the dorsally hooded foreskin, whereas in other countries foreskin reconstruction is preferred so that the penis looks unoperated. However, many ethnic groups in the United States do not prefer routine circumcision.

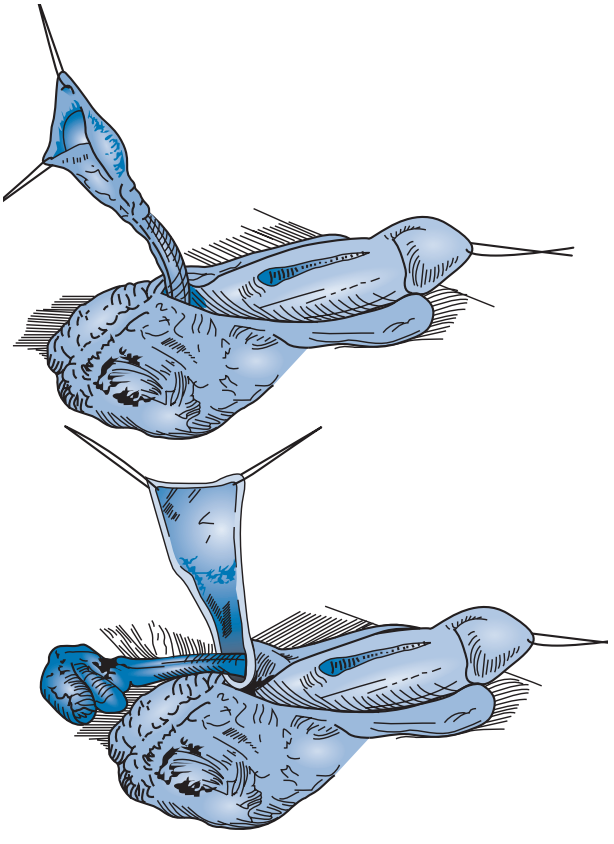

Figure 71.27 Dorsal buccal inlay hypospadias reoperation.

Whenever possible, hypospadiologists should offer families the outcome they desire. If the TIP repair is performed, surgeons can reconstruct the foreskin without increased complications unless there is ventral curvature more than 30° or urethroplasty using preputial skin is anticipated. The main difference between repairs with circumcision is that the initial skin incision does not extend circumferentially, but from the dorsal corners of the hooded prepuce ventrally under the meatus (see Figure 71.12). The ventral shaft is degloved to healthy dartos. After urethroplasty, the prepuce is approximated in three layers, consisting of inner prepuce, middle dartos, and outer skin. The reconstructed foreskin is not manipulated until these suture lines have healed, usually between 6 and 12 weeks. Secondary phimosis is uncommon, and although dorsal dartos is not accessible for a barrier layer, the rate of fistulas has not been increased.[112–114]

Suture tracks have occurred in as many as 40% of patients after hypospadias repair when stitches are placed through the epithelium.[115] These may not be apparent for as long as 1 year postoperatively, as desquamated keratin fills the small tunnel remaining after the sutures dissolve. We advocate use of subepithelial stitches to minimize suture tracks, although they can still occur despite this precaution from the passage of needles through skin appendages.

Two-stage repair

We occasionally encounter challenging cases where severe chordee and a proximal meatus limit the applicability of a one-stage tube repair. In a few cases, injury to the vascular pedicle of the onlay or tube during harvest requires a two-stage repair. Anecdotal and reported experience maintains, in fact, that the two-stage technique offers fewer complications overall and better cosmetic results than the single-stage repair for select cases.[116,117] Our CHOP experience, however, suggests a similar fistula rate following the second stage of a two-stage repair to that following a one-stage island onlay or tube repair.[97]

A two-stage repair often involves a scrotoplasty with an aggressive attempt to relieve penile curvature, including transection and proximal removal of the plate. Either a dermal graft or tunica vaginalis may bridge a gap over an incised Buck's fascia, although this maneuver is very rarely required to bridge any defect in the ventral tunica albuginea surface. Traditionally, the dorsal hooded preputial skin is incised to rotate the resultant flaps ventrally. These flaps are allowed to heal and will be used to create the future urethral plate. Alternatively, an island flap can be sewn into place to be used as a urethral plate later.

The second stage is planned after an interval of about 6 months. At that point, parallel vertical incisions 12–15 mm apart are mapped distally, beginning at the meatus and including the glans. Glans wings are mobilized and the glans may be incised in the midline as with the TIP repair. Incisions are completed and a neourethra is then tubularized to complete the repair using a standard Thiersch–Duplay technique. We cover the repair aggressively with dartos tissue or in some cases with processus vaginalis flaps taken adjacent to the spermatic cord on one side or the other. Rarely, placement of the suture line into the scrotum facilitates healing. The penis is then mobilized from the scrotal flaps in a third stage, usually 3–12 months later.

Grafts

Severe proximal hypospadias and repeat hypospadias repairs may incorporate free grafts to construct a neourethra or augment an existing plate. The versatility of most primary hypospadias repairs using

preputial skin or the urethral plate, however, has obviated our use of free grafts for primary hypospadias repairs. At CHOP, we reserve this technique only for reoperations or the rare instances where a paucity of local tissue is evident.[118] Free skin, bladder mucosa, tunica vaginalis, and buccal mucosa have been variously described as appropriate tissue for free graft use.[119–121]

Our experience has been that bladder mucosa is less pliable than buccal mucosa, with the latter being less likely to shrink and requiring a one-to-one ratio for harvest compared with the defect to be repaired. We prefer buccal mucosa also, as thick epithelium, tensile strength, and high levels of type IV collagen favor graft take.[122] We no longer use bladder mucosa and use buccal mucosa exclusively in the rare cases requiring a free graft. Our techniques are similar to those described above. We no longer advocate the use of tubularized buccal mucosal grafts, but prefer staged repairs, as described above.

Metro et al[118] and Hensle et al[98] have reported long-term results for buccal mucosa used as tubularized repairs in complex hypospadias reoperations. Overall complication rates of from 32% to 57% were reported, with graft stricture and meatal stenosis being most common. All complications were evident by 11 months in both groups Buccal mucosa is a viable non-genital tissue alternative for a select subgroup of patients requiring urethral reconstruction, but superior results seem likely if the graft is staged.

Reoperative urethroplasty

Differences in opinion between the authors regarding primary hypospadias repair also influence our recommendations for reoperations.

WTS [first author]: The goal in hypospadias reoperation is the same as in primary surgery, which is a functional penis with a normal cosmetic appearance. I follow the same decision-making process – tubularizing the urethral plate when it is still present and supple, and otherwise creating a neourethral plate for tubularization. As in primary urethroplasty, skin flaps are avoided, especially since their vascularity cannot be assured after prior surgery.[123]

During the past 20 years the trend in primary hypospadias repair has been to conserve the urethral plate for use in urethroplasty. Consequently, in my experience, the plate is most often still present after one or two failed operations. Furthermore, despite prior incision for MAGPI or TIP, the urethral plate may remain grossly supple. We perform cystoscopy before surgery to determine the status of any remnant neourethra or the distal native urethra. Then we outline a Y-shaped incision along the visible junction of the glans to urethral plate, extending 2 mm under the meatus and then continuing in the midline to near the penoscrotal junction. We then incise and tubularize the urethral plate. We mobilize a flip-flap of dartos from the ventrum to cover the neourethra before glansplasty. If a dartos flap is not available, we use tunica vaginalis, since fistulas are more likely without

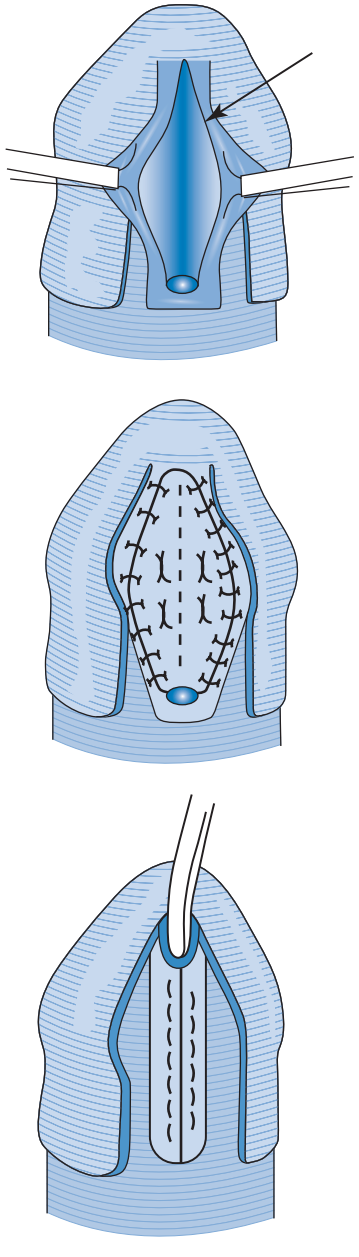

Figure 71.28 Patch grafting regions of focal scar in staged buccal graft urethroplasty. The scarred region is excised and replaced with new buccal graft quilted into place.

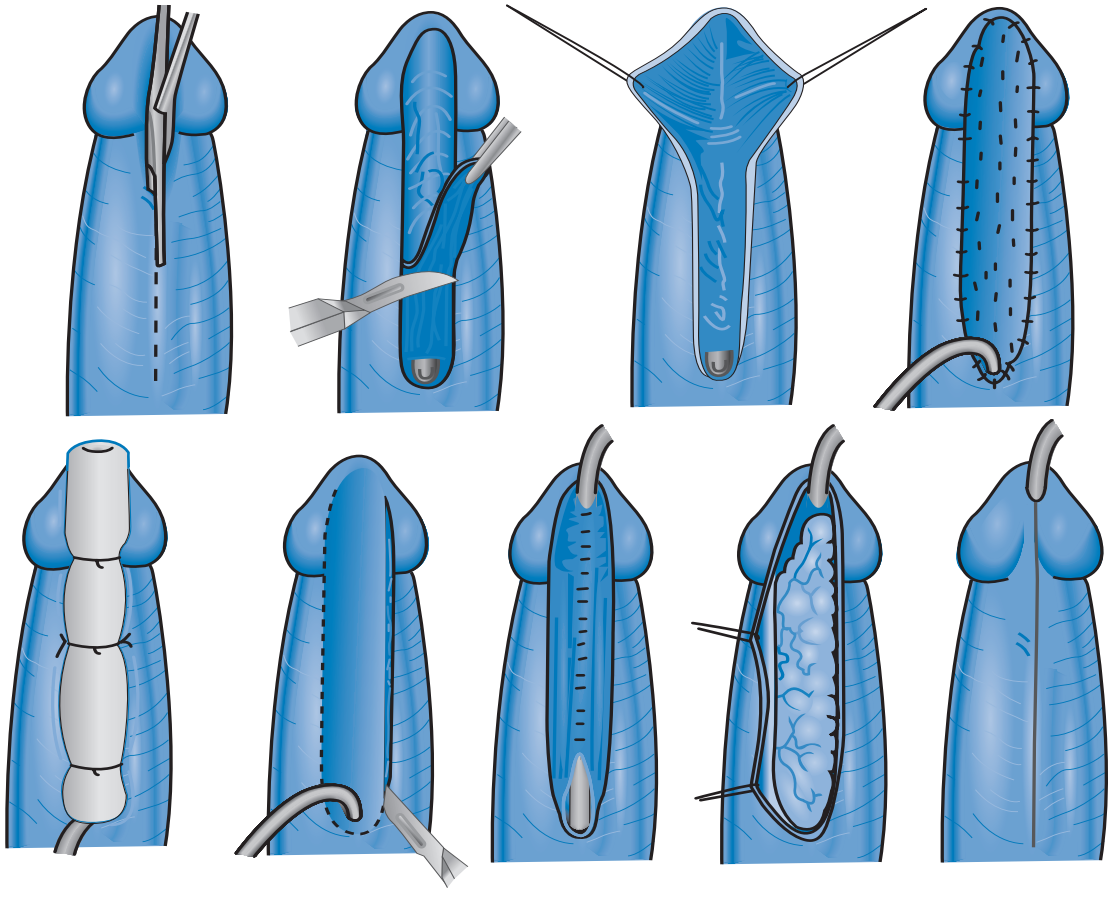

Figure 71.29 Staged buccal graft hypospadias reoperation.

coverage of the urethral reconstruction with a barrier layer.

If the urethral plate was excised previously, a healthy skin strip can sometimes be conserved as a substitute urethral plate. It is incised in the midline, but rather than rely upon spontaneous re-epithelialization, the resultant defect is grafted with buccal mucosa (Figure 71.28). We quilt this buccal inlay graft into place, and then tubularization proceeds for a single-stage repair. Dorsal inlay grafting mimics current trends in adult urethral stricture repair, taking advantage of the reliable take that occurs when a graft is secured dorsally to the corpora.

When there is gross scarring of the urethral plate or residual skin, or any evidence of balanitis xerotica obliterans (BXO), we excise these tissues and replace them with buccal graft for staged urethroplasty (Figure 71.29). In the first operation, we excise unhealthy tissues from prior surgery from the surface of the corpora and between the glans wings, re-establishing a deep glans groove. We create a proximal urethrostomy and we harvest a buccal graft. We use the inner lip to resurface the glans, while cheek covers the penile shaft.

Following the first stage, focal contraction or scar develops in up to 20% of patients. Midline incision and buccal inlay grafting during the planned second-stage urethroplasty can correct partial graft contracture. More extensive contracture or scarring requires a second operation to excise the unhealthy region and regraft (Figure 71.30). Urethroplasty is then performed 6 months later.

At the second stage, margins of the neourethral plate are first infiltrated with 1:100 000 epinephrine. Then the buccal plate is separated from the shaft skin and glans. It is tubularized, turning epithelium into the lumen. I prefer to use a two-layer closure, the first with interrupted and the second with running stitches. We cover the entire neourethra with dartos and/or tunical vaginalis flaps, and then glanuloplasty and shaft skin closures proceed as described above for primary repairs.

A 6 or 8 Fr dripping stent provides urinary diversion in prepubertal boys, but in teens and adults we leave a 10 or 12 Fr stent across the repair with a percutaneous suprapubic tube for urine drainage. We continue diversion for 10 days, and cover with

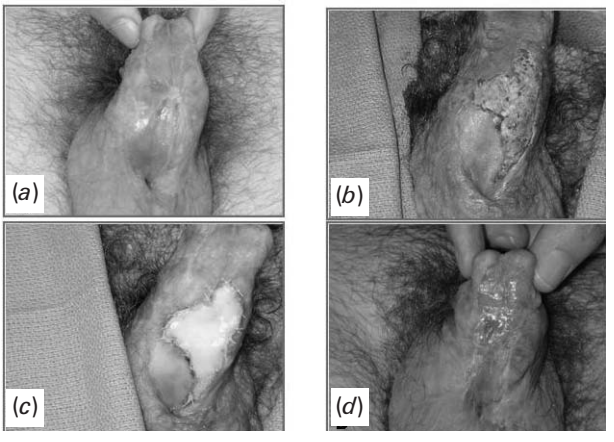

Figure 71.30 (*a*) Scar noted in mid portion of graft. (*b*) Scarred region is excised. (*c*) Scarred region is replaced with new buccal graft quilted into place. (*d*) Patched area now healed, neourethral plate ready to be tubularized.

antimicrobial prophylaxis using trimethoprim–sulfamethoxazole. We have usually prescribed antiandrogens in teens and adults to reduce erections.

Staged buccal graft reoperations result in a vertical slit meatus while preserving penile skin for shaft closure. Consequently, excellent cosmetic outcomes have been achieved despite as many as 15 prior failed operations.[124] Fistulas were noted in only one case in which a tissue barrier layer covered the neourethra, and no strictures or diverticulum occurred.

DAC [third author]: In redo hypospadias repairs, our modification of the flap harvest has led us to feel more confident in harvesting distal penile shaft skin in patients who have already had the foreskin utilized in previous repairs and even in a reharvest of shaft skin following the previous harvest of an island flap in the initial repairs.

Because of the difficulty and high risk of fistula, particularly in the older patient, we prefer to get as much tissue to the ventral penile shaft as possible; hence our commitment to moving tissue, to covering the fistula in most cases with skin taken from the dorsum of the penis on a pedicle flap. If the urethra requires replacement, we separate the flap with half of the flap deployed as the urethral replacement and the other half of the flap used as ventral skin coverage. Successful urethroplasty for a patient that has undergone previous failed hypospadias repairs remains a surgical challenge. These repairs require continued adherence to the surgical principles of urethrocutaneous fistula repair: a sufficient time interval following failed repair; excision of the fistulous tract; closure of the urethral defect with mucosa-inverting sutures; and overlay of the urethral repair with abundantly vascularized tissue.[125] In some cases, however, the absence of preputial skin, paucity of ventral skin, and residual chordee may all contribute to augment the risk of failure following salvage hypospadias surgery.

The split onlay skin (SOS) flap for redo hypospadias repair or fistula

We have attempted to address the dual aims of completing a redo urethroplasty with an onlay island flap using residual penile skin while also rotating adequate skin for ventral penile skin coverage. We place a glans traction suture and mark a circumcising incision line. The line extends ventrally to the midline and then vertically to the penoscrotal junction. The release of this ventral tissue allows the dorsal skin to flatten in an 'open-book' fashion, facilitating proximal dartos mobilization with the island skin flap with minimal risk of damage to the pedicle to the dorsal skin flap. Lidocaine with epinephrine (1:100 000) is infiltrated along the marked line prior to incision. We then deglove the penis by creating a plane of dissection superficial to Buck's fascia and avoiding injury to the preputial skin pedicle (Figure 71.31a).

If the distal urethral coverage is particularly thin, or if a diverticulum is present along with a fistula, we incise the urethra distal to the fistula, from distal to proximal, and the diverticulum is trimmed. If the distal urethra requires reconstruction, we measure the length of the urethral defect to estimate the size of the skin flap that will be required for urethroplasty. We then examine the dorsal penile shaft skin for redundancy, and outline a circumferential flap up to 1 cm wide and longer than the length of the urethral defect. We place interrupted 5–0 polypropylene stay sutures and grasp them so that we accentuate the fold of tissue between the outlined flap skin and the shaft skin. We divide the epithelium with the initial incision and harvest the flap in a plane that preserves the vascular pedicle. The midline incision of the ventral shaft skin completed earlier releases the base of the dorsal vascular mesentery and facilitates flap mobilization.

We then pass the dorsal penile skin flap over the glans through a buttonhole in the mesentery. We divide the flap transversely into superior and inferior segments after ensuring adequate vascularity to both segments (Figure 71.31b,c). We tailor one part of the flap to fit the urethral defect. We suture the urethral segment into place with interrupted 7–0 polyglactin sutures as an island onlay hypospadias repair (Figure 71.31d). After we reconstruct the glans, we place a

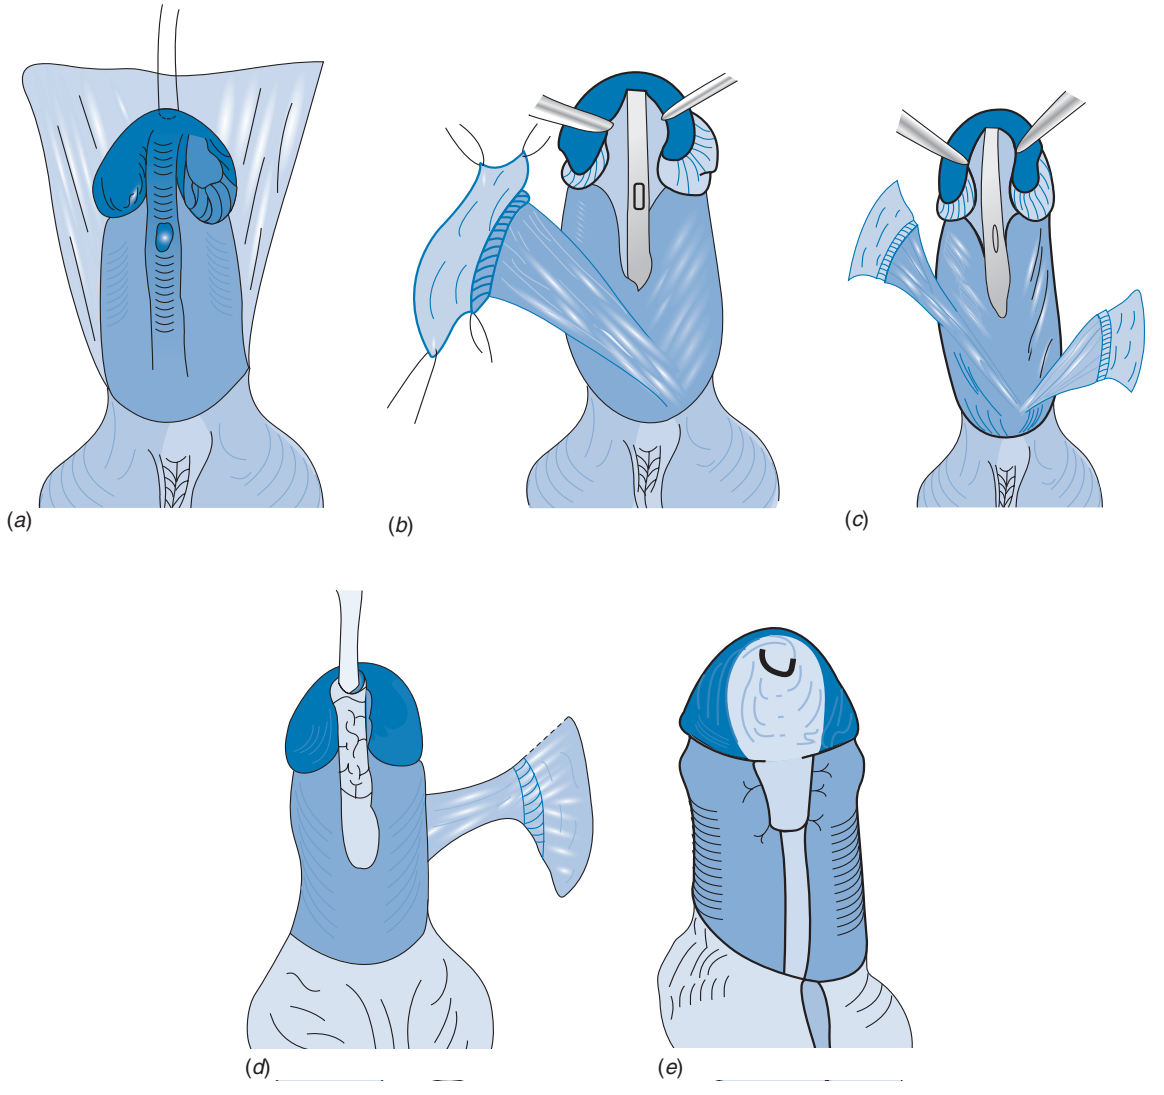

Figure 71.31 The split onlay skin (SOS) hypospadias repair technique. (*a*) The fistula is identified along the ventral surface of the penile following circumferential degloving of the penile skin. (*b*) An approximately 1 cm wide dorsal preputial flap is isolated and harvested, preserving the vascular mesentery. A buttonhole is created in the mesentery and the flap is transposed ventrally. (*c*) The flap is divided transversely into two segments, with the superior segment tailored to correspond to the urethral defect and to be used as an onlay flap. (*d*) The appropriately designed superior segment is sutured into place with interrupted 7–0 polyglactin sutures, as in the standard island onlay hypospadias repair, and a glanuloplasty is completed over a 6 Fr Kendall stent. (*e*) The residual penile skin is reapproximated dorsally and the remaining inferior segment of the rotated flap is used to cover the persistent ventral skin defect.

6 Fr urethral stent and begin the skin closure. A redundant dorsal prepuce is not available in these boys to use to cover the ventral skin defect. Therefore, after reapproximating the dorsal penile shaft skin, we tailor the remaining segment of the dorsal skin flap to provide additional coverage of the ventral penile shaft (Figure 71.31e). A Telfa and gauze dressing that compresses the penis and urethral stent against the lower abdominal wall with Tegaderm ('sandwich dressing') is applied and the patient is discharged with prophylactic antibiotics.

Our preference is to preserve the urethral plate, if possible, and utilize penile skin in repairing the failed hypospadias repair. Our experience has been similar to the reports of Jayanthi et al[123] and Simmons et al[126] that previously relocated penile skin may be successfully rotated as an island onlay flap to repair hypospadias fistula without vascular compromise and with consistently favorable outcomes. We have found that even following multiple previous hypospadias repairs, enough penile shaft skin is usually present dorsally or laterally to transpose ventrally for an island onlay repair.

We have also used acellular dermal matrix (AlloDerm) to augment the flap in cases where the dartos coverage is thin. In complex hypospadias cripples, we have also used this material in conjunction with primary closure or in association with flaps.

Complications of hypospadias repair

Fistulas

Urethrocutaneous fistulas are the most common complication of hypospadias surgery. Several factors have been implicated in their occurrence, including apposing suture lines from neourethral and skin closure, distal obstruction from meatal stenosis or urethral stricture, turbulent urine flow, for example in diverticulum, and locally impaired vascularity. Fistulas are usually apparent within the first few months after surgery, but occasionally develop years later. Some close spontaneously, but most require surgical correction.

Barrier layers to 'waterproof' the neourethra separate overlying suture lines to decrease risk for fistulas. Although helpful, this measure alone is not sufficient, as seen in our report of a 21% incidence of fistulas in proximal repairs despite the use of a dartos barrier flap in every case.[93] In this series no attempt was made to turn epithelium into the lumen of the neourethra and, since making this modification, the fistula rate has diminished by more than 50%.

We have delayed fistula repair for 6 months and longer after hypospadias surgery in older children and adolescents to allow postoperative edema and tissue inflammation to resolve. We perform urethroscopy or sound the urethra to assess the neourethra for obstruction, diverticulum, or unexpected additional fistulas. The surgical field is infiltrated with 1:100 000 epinephrine to minimize bleeding for optimal visualization, and then the fistula opening is circumscribed and the tract dissected to the entrance into the urethra. After excision, we turn back the epithelium of the urethral opening into the lumen, and this closure is then covered with a dartos flap. Fistulas at the coronal margin or on the proximal glans require more extensive repair, opening the distal urethra from the meatus through the fistula. In these cases, we redo the hypospadias with closure of the neourethra, interposition of a dartos flap, and glanuloplasty. Although catheter drainage in not always needed after closure of small fistulas on the penile shaft, we recommend it following reoperative glanuloplasty.

Immediate treatment to seal fistulas was reported in a small series of patients in whom topical corticosteroid was initially applied for 3 days to reduce tissue reaction, and then a catheter was placed and n-butyl cyanoacrylate applied.[127] Durable success, defined as no recurrent fistula at 6 months, was noted in five of eight cases, but the potential role of early therapy will require additional experience.

Small fistulas amenable to simple closure, including coverage with a dartos layer, are successfully repaired in over 90% of cases,[128,129] although larger and multiple fistulas have a higher recurrence rate,[129,130] which may indicate impaired local vascularity. If the neourethra appears otherwise healthy, we would expose the affected area with a more extensive dissection and supplement any available local dartos flap with an additional covering using a tunica vaginalis flap.[131]

Meatal stenosis

Meatal stenosis may result from poor distal vascularity and wound contracture, technical errors in meatoplasty, or less commonly, from BXO. Regardless of urethroplasty technique, the neomeatus should be generously sized and oval, not rounded, allowing for minor postoperative contraction. This precaution applies especially to tubularization procedures where the temptation to suture the neourethra too far distally can lead directly to stenosis. Failure to incise a narrow, flat urethral plate for TIP repair could also result in an inadequate diameter. BXO is not commonly encountered after hypospadias repair in the United States, possibly because of the preference for circumcision, but should be suspected when a typical white scar involves the meatus.

A visually small meatus is not necessarily pathologic, and calibration should be performed to diagnose true stenosis. Meatotomy may be an effective therapy for a limited distal scar, or reoperative glanuloplasty with deep urethral plate incision may be required to increase the distal urethral caliber. BXO occasionally responds to topical corticosteroids, but usually mandates complete excision of the involved tissues with buccal mucosal grafting.[132]

Urethral stricture

We suspect a neourethral stricture when the urinary stream is diminished, although a visibly decreased force of the stream and uroflowmetry in the lower limits of normal can occur despite an adequate urethral diameter determined by urethroscopy and calibration.[88] Circumferential anastomoses are thought

to have a greater risk for constriction, but a comparison study of tubularized vs onlay preputial flaps found no significant difference in strictures between the two techniques.[106] Despite initial concerns that the relaxing incision for TIP would create strictures, this complication has only been rarely encountered.[88,92]

Short strictures detected within a few months of surgery can be managed successfully with dilation under anesthesia or optical urethrotomy, with reported success in approximately 50% of cases.[133] However, these interventions are only successful in 16–21% of cases when strictures are detected later.[133,134] Because strictures probably indicate regions of compromised vascularity, we usually recommend open repair incorporating healthy tissues. Following the example of adult stricture repair, it may be preferable to open the diseased area longitudinally to healthy margins and then incise dorsally through the entire stricture, filling the defect with buccal graft. Extensive stricture of the neourethra should prompt consideration for reoperative urethroplasty.

Diverticulum

Diverticulum presents with visible ballooning during voiding and postvoid dribbling. Etiologies include distal obstruction, turbulent flow, and creation of too large a neourethra. Genital skin is elastic to allow erection, and so may balloon proximally from fixed resistance of the non-distensible glanular urethra without anatomic obstruction. Accordingly, Greenfield et al[135] reported a 21% incidence following staged preputial repairs, whereas in a personal series of six patients undergoing staged Byars flap–glanular TIP urethroplasty, diverticulum developed in four cases despite care to avoid making skin flaps wider than 12 mm. A significantly decreased incidence of diverticulum was reported by Weiner et al[106] after onlays rather than tubularized preputial flaps, probably reflecting the use of less genital skin. To our knowledge, diverticula have not been reported after buccal graft urethroplasty, which probably reflects the difference in elasticity of this tissue compared with genital skin.

After excluding distal obstruction, correction involves excision of redundant tissue to restore a normal urethral caliber. Recurrent diverticulum is uncommon.

Dehiscence

Partial or complete dehiscence of the glans has probably been under-reported, or characterized as meatal regression. This wound separation could result from infection, poor vascularity, and/or tension on the repair. In addition, one of us (WTS, unpublished data) has noted that choice of suture material and closure technique for glanuloplasty was related to the incidence of this complication. Among the initial 131 patients undergoing TIP repair, 7–0 chromic mattress sutures were used to approximate glans wings, with a subsequent 5% partial or complete separation. When subepithelial 6–0 polyglactin was substituted in the next 156 cases, the rate of glans dehiscence decreased to 2.5%. Furthermore, since the glanuloplasty technique was changed so that the ventral lip of the meatus was sutured first and not sewn to the underlying neourethra, there has been no dehiscence in a subsequent 75 distal cases.

Recurrent penile curvature

There are very limited data regarding long-term results of currently used techniques for correcting penile curvature. The most important question is whether the straightening achieved in childhood is maintained during puberty, and to date no reports document such outcomes for dorsal plication or the various forms of ventral corporeal grafting.

Baskin and Duckett performed dorsal plication in 182 boys, most during the first year of life, using transverse incisions into the tunica albuginea lateral to the neurovascular bundles. Curvature was diagnosed by artificial erection after shaft skin degloving, and straightening then confirmed after plication by repeat injection. With mean follow-up of 2.7 years, 4% of the boys had recurrent curvature. Only one patient was deemed to have sufficient bending to warrant repeat surgery, and failure in this case was attributed to plication without incision into the tunica albuginea.[136] Nevertheless, Baskin subsequently abandoned this technique for midline plication without tunic incision to minimize potential iatrogenic injury to the sensory nerve complex.[28] In one series[138] of boys undergoing midline plication using one–two stitches of 4–0 or 5–0 polypropylene, 97% of boys with curvature $<45°$ had a straight penis with a median follow-up of 16 months. There were four patients with $>45°$ bending, of which two had persistently severe curvature, leading the authors to recommend other techniques for straightening be used for this extent of curvature.

A survey of pediatric urologists in the United States reported increased reliance on division of the urethral plate and ventral corporeal grafting for curvature $>40°$.[138] Dermal grafts have most commonly been

used to repair the defect created by incising the tunica albuginea of the corpora cavernosa, with straightening achieved in >90% of patients.[79,80] Tunica vaginalis grafts were also reported successful for penile straightening,[81,82] although Caesar and Caldamone[78] noted recurrent curvature in 60% of patients after tunica vaginalis grafting while no patient had bending following dermal repair. Two studies report the use of single-layered small intestinal submucosa (SIS) for corporeal grafting in a total of 24 patients, with straightening confirmed in each by repeat erection during second-stage urethroplasty.[83,84] However, recurrent curvature from graft contracture occurred in two of 12 boys repaired with four-layer SIS.[139]

Contracture of the neourethra can also result in ventral curvature. As mentioned above, this complication occurred in one patient following tubularization of an 'unhealthy' incised urethral plate. Vandersteen and Husmann[140] reported similar contracture of prior tubed graft urethroplasty resulting in curvature in a small series of men evaluated after puberty. Penile tethering in this circumstance requires transection of the neourethra for straightening.

Shaft skin complications

Suture tracks result from epithelialization around suture material before its dissolution. Given the small diameter of sutures currently used for skin closure in hypospadias surgery, it may take as long as 1 year following repair for keratin to fill the sinus and thereby become visually apparent. Consequently, the incidence of this minor complication is unknown and most probably underestimated, but it was reported in 43% of a small series of boys and prompted a recommendation that subepithelial stitches be used.[115] Correction involves unroofing the skin tunnel using sharp pointed scissors.

Secondary phimosis or wound dehiscence can occur after foreskin reconstruction. Most series have noted few such complications,[112–114] although one European center reported 14% dehiscence and increased fistula development.[141] We advise parents not to manipulate the foreskin postoperatively until the surgeon first ascertains sufficient wound healing has occurred 6–12 weeks later to minimize concerns for iatrogenic disruption of the suture line. Although secondary phimosis rarely occurs, when suspected, application of 0.05% betamethasone twice daily to the tip of the prepuce may be advised to ensure it can subsequently be retracted.

Secondary phimosis can also occur following circumcision, usually from a combination of shaft skin swelling and peripenile fat tending to elevate the skin. Steroid creams may resolve the issue, or reoperative circumcision is needed. Sutures tacking skin to the penile shaft dorsally and ventrally may help prevent this complication if there is concern that excess prepubic fat will push the penile shaft skin over the glans.

Abnormalities of the penis and scrotum

72

Michael F MacDonald, Julie Spencer Barthold, and Evan J Kass

Introduction

Anomalies of the genitalia are common and as a group constitute the most frequent cause of birth defects in males. However, other than cryptorchidism and hypospadias, the majority of congenital malformations of the testis and scrotum are extremely rare and are often associated with anomalies of other organ systems. Fortunately, most of these anomalies are identified at birth and some are occasionally detected in utero.[1] Many other developmental abnormalities affecting the genitalia, such as patency of the processus vaginalis (hernia and/or hydrocele), varicocele, and the bell clapper deformity of testicular suspension, may not be apparent for many years but have the potential for significant long-term morbidity. For most genital defects the etiology remains unknown. Congenital and acquired pediatric abnormalities of male genitalia, excluding intersex disorders, hypospadias, and cryptorchidism, are reviewed here.

Normal development of the penis and scrotum

The external genitalia, including the genital tubercle and labioscrotal swellings, are indistinguishable in the male and female before the 9th week of human gestation.[2] Subsequent development in males proceeds in a proximal to distal fashion. The urethral groove deepens and the urethral folds become distinct and then fuse in the midline. Recent work suggests that creation of the glanular urethra also occurs by fusion of the urethral plate, via the mechanism of epithelial–mesenchymal interaction, and not by the previously suggested ingrowth of surface glanular epithelium.[2–5] The paired labioscrotal swellings attain a more ventral position, either by actual migration or by relative change in position due to lengthening, and are anterior to the genital tubercle by 11 weeks of gestation. Fusion of the urethra up to the coronal sulcus is complete by 12 weeks. Developmental penile curvature is lost and scrotal positioning complete by 13 weeks. Fusion of the urethral folds within the glans proceeds as described for urethral closure in the shaft, and is accompanied by distal growth of the prepuce. By 24 weeks, the meatus is at the glans tip and the prepuce completely covers the glans, to which it is largely adherent.

Penile abnormalities

Prepuce

Normal development

At birth, the normal prepuce is usually unretractable because of physiologic adherence between the glans and inner preputial skin and/or tightness of the preputial ring. Ease of retractability of the prepuce increases with age, with complete retraction possible in at least two-thirds of 11–15-year-old and 95% of 16–17-year-old uncircumcised males.[6–8] Therefore, true phimosis is present in childhood only in cases of secondary fibrosis or balanitis xerotica obliterans of the prepuce, which occur in 0.8–1.5% of uncircumcised boys.[9]

Circumcision

The prevalence of routine neonatal circumcision in the USA has dropped from close to 90% in the mid-1960s to an estimated 64% in 1995.[10,11] Epidemiologic data indicate that there are marked differences in

circumcision rates based on socioeconomic class, ethnicity, and religious affiliation. The most recent American Academy of Pediatrics (AAP) Task Force on Circumcision report (1999) supports a growing trend away from neonatal circumcision. However, the degree of controversy surrounding this issue is made clear by the shifts in AAP policy over the last 25 years. In the most recent report, the AAP Task Force acknowledges potential medical benefits to neonatal circumcision but concludes that these do not warrant its routine use. Benefits include reduction in the risk of urinary tract infection (UTI) in infant males and development of penile cancer as an adult. For example, uncircumcised infant boys are three to ten times more likely to develop a UTI than circumcised male infants, probably because of an increased rate of periurethral and inner preputial bacterial colonization.[11] Similarly, penile cancer occurs almost exclusively in uncircumcised males. However, penile hygiene, including foreskin retraction with periodic cleansing, may also be preventive. Nevertheless, both of these conditions are rare and their prevention by routine circumcision may not be justified. The argument that the risk of sexually transmitted disease is reduced by circumcision is not supported by available data.[10,12]

Similarly, the risk of penile problems of sufficient severity to require circumcision is low.[7,9,11] Balanitis and balanoposthitis, characterized by erythema, edema, and purulent preputial discharge involving the glans and/or prepuce, occur in 3–10% of uncircumcised boys. Paraphimosis, or retraction of a tight preputial ring with consequent severe glanular edema, is rare. Circumcision may be necessary only when these problems are severe or recurrent. However, even in these boys the use of topical steroids can significantly reduce the need for circumcision.[13] Since circumcision in older boys requires general anesthesia and may be associated with morbidity,[14] it should not be performed without discussing the option of medical therapy.

Newborn circumcision is performed with the Mogen or Gomco clamp or the Plastibell device.[15] Contraindications include hypospadias, chordee, penoscrotal fusion, buried penis, micropenis, and bleeding disorders. Complete separation of the prepuce from the glans with circumferential visualization of the corona is essential for adequate and safe newborn circumcision. Since significant physiologic response to pain has been documented in neonates undergoing circumcision, local anesthetic should be used.[11] Choice of anesthetic technique depends on the skills and experience of the surgeon, although penile ring block may be the easiest and most effective alternative.[16] Older infants and children are circumcised under general anesthesia using a freehand sleeve resection technique.

Complications of circumcision

The risk of complications after circumcision is 0.2–5%.[15] Bleeding is most common, occurring in 0.1% and more often in older boys, but is usually self-limited. Infection typically responds to local care but in rare cases may be associated with sepsis, necrotizing fasciitis, or death. Other complications of varying severity may occur, some of which may require further surgical intervention. Partial denudation of the penile shaft due to removal of an excess amount of skin will heal uneventfully with local wound care alone. Further intervention is required only to correct secondary chordee or phimosis. Conversely, excess or 'redundant' preputial skin remaining after circumcision is often a source of concern for parents but surgical intervention is rarely required. Resolution of physiologic adherence between the remaining skin and the glans will occur spontaneously after puberty, as in uncircumcised boys. Contracture of the healing edges of skin over the glans may produce secondary phimosis, also known as a trapped penis (Figure 72.1a). Correction requires excision of scar and in some cases penile skin flaps or Z-plasty for closure. Skin bridges (Figure 72.1b) between the shaft and glans may cause chordee and should be sharply incised. Inclusion cysts (Figure 72.1c), comprising retained subcutaneous epithelium, should be completely excised. More severe injuries include glans amputation (Figure 72.1d), which can often be repaired acutely with success. However, subsequent meatal stenosis may require delayed urethroplasty.[17] Total penile necrosis (Figure 72.1e) is a rare but devastating complication of circumcision that is usually the result of using an electrocautery in combination with a metal clamp, such as a Gomco. The use of electrocautery for circumcision is safe as long as it is not used in combination with a metal clamp.[18] Some investigators have recommended gender reassignment[19] for children with penile necrosis. However, male gender identity may be a consequence of testosterone imprinting, suggesting that gender conversion might be unsuccessful.[20]

Meatal stenosis occurs almost exclusively in circumcised boys. The proposed etiologies include frenular devascularization or chronic meatitis from exposure of the unprotected meatus to diaper irritation.[21,22]

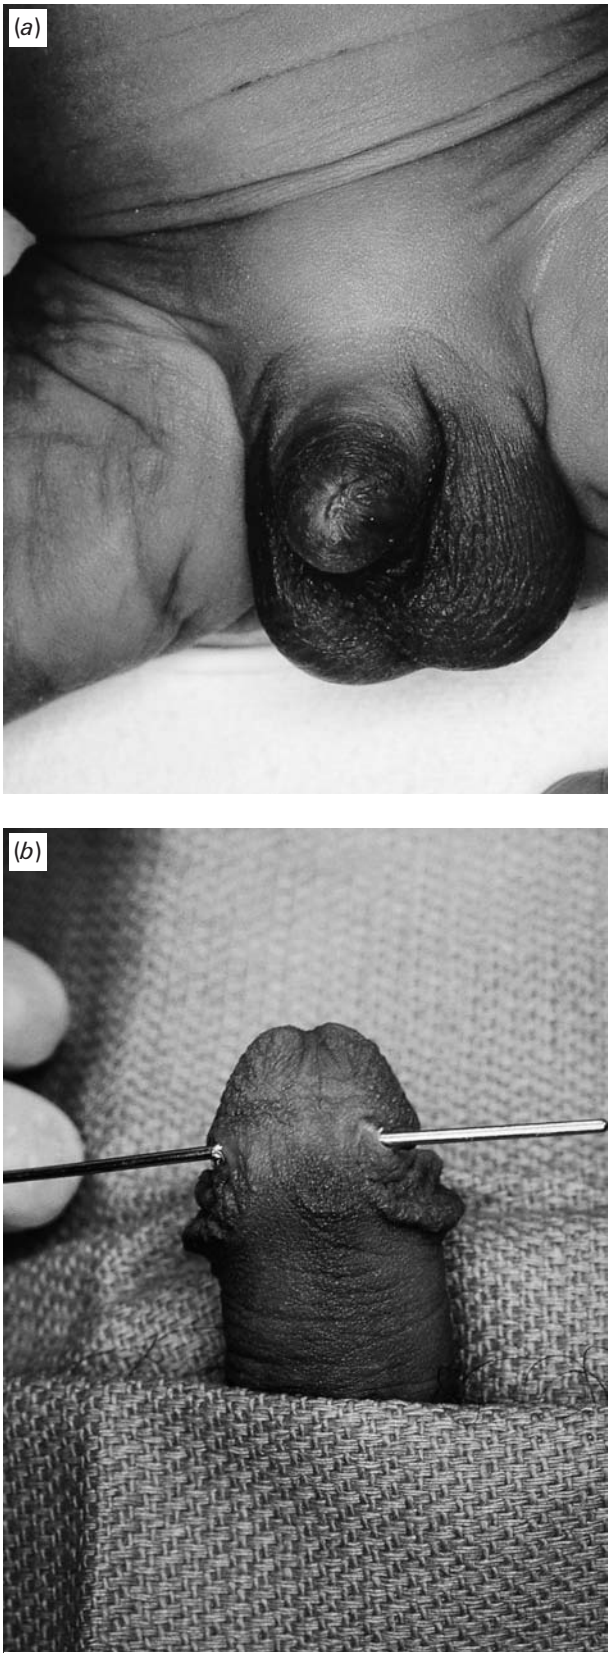

Figure 72.1 Complications of neonatal circumcision: (*a*) secondary phimosis; (*b*) skin bridge between glans and penile skin; (*c*) penile cyst; (*d*) glans amputation; (*e*) penile necrosis.

Figure 72.2 Upwardly deflected urinary stream in a boy with significant meatal web.

The incidence of symptomatic meatal stenosis after neonatal circumcision appears to be <10%, based on limited available data.[21,23] Non-specific symptoms such as urethral bleeding, dysuria, or other voiding complaints may be present, but the pathognomonic finding is upward deflection of the urinary stream as a consequence of an acquired ventral web (Figure 72.2).[24] Urinary tract imaging is unlikely to disclose significant pathology in the absence of incontinence or UTI. Meatoplasty or meatotomy can be performed under a brief general anesthetic or in the office after a generous application of EMLA cream[25] (see Chapter 10).

Defects of number or position

Penile agenesis

Penile agenesis, or aphallia, is complete absence of the penis in an otherwise normal phenotypic and genotypic male (Figure 72.3).[26,27] Rudimentary erectile tissue is occasionally present. The estimated incidence is 1 in 10–30 million and the presumed etiology is absence or failed development of the genital tubercle. The majority (54%) of patients have other genitourinary anomalies (e.g. cryptorchidism, renal and/or ureteral malformations) with or without gastrointestinal, musculoskeletal, and cardiovascular anomalies. Skoog and Belman[27] classified patients based on the relationship of the urethral meatus to the anal sphincter, noting increased additional anomalies and mortality with more proximal location of the meatus. The three variations that they described, in decreasing order of frequency, are postsphincteric with anterior perianal urethra, presphincteric with urethrorectal fistula, and urethral atresia with vesicorectal fistula. Treatment for these patients is controversial. Surgical

Figure 72.3 Aphallia in a patient with a perianal urethral opening identified by sound.

intervention during infancy, including urethral transposition and bowel vaginoplasty via a posterior sagittal approach plus orchiectomy and scrotoplasty, has been advocated.[28,29] However, gender reassignment in other contexts and detailed psychosexual data may not support this recommendation.[26,27,30–35] In addition, since phallic reconstruction is feasible, if imperfect, in prepubertal boys,[36] maintenance of male gender should be considered an option in discussions with the patient's family (see Chapter 68).

Diphallia

Penile duplication or diphallia occurs in an estimated 1 in 5–6 million births.[37–39] The proposed etiology is branching or splitting of the genital tubercle soon after the 5th week of gestation. A balanced genetic translocation involving chromosomes 1 and 14 has been reported in one case.[40] Variants include partial and complete forms of true diphallia and bifid phallus. In

the bifid variant, which is more common, the penis is branched at any point along its length, with each shaft containing a single corpus cavernosum. The designation of true diphallia is reserved for cases in which an accessory tricorporal penis (both cavernosa and spongiosum present), which may be hypoplastic, is present. The accessory organ may be located in the perineum or upper thigh. Ultrasound may be useful to characterize corporeal anatomy.[37] Associated malformations are usually present and may include urethral duplication or agenesis, bladder duplication or exstrophy, hypospadias, epispadias, widened symphysis, cryptorchidism, and/or anorectal, renal, or scrotal anomalies. Also, cardiac and musculoskeletal anomalies have been reported.[41] Surgical repair involves excision of one completely duplicated penis or fusion of the bifid penes with urethral reconstruction.

Abnormal development

Penile torsion

Rotational deformity of the penis, usually in a counterclockwise direction, is most often associated with hypospadias and chordee but may occur as an isolated abnormality.[42] The incidence in a cohort of normal newborn males was 1.5%, with curvature of at least 90° seen in 0.7%.[43] Deviation of the median raphe without torsion was noted in 10% of newborns. Although a functional abnormality is absent if the penis is straight, penile torsion can be corrected in most cases by penile skin degloving and realignment. For the more severe cases this may be ineffective and other procedures, such as a dorsal dartos flap rotation, may be utilized.[44]

Penoscrotal fusion

Foreshortening of an otherwise normal ventral penile shaft occurs when the ventral penoscrotal junction is located distal to its normal position (Figure 72.4).[45,46] This abnormality is called penoscrotal fusion or webbed penis, and may be congenital, due to removal of excess ventral skin during circumcision, or associated with hypospadias. Large, bilateral hydroceles in infancy may cause apparent penoscrotal fusion, which disappears with resolution of the hydrocele.[45] Lengthening of the ventral shaft is most simply accomplished by preputial unfurling with or without ventral transfer of dorsal preputial skin. If the foreskin is not tight, use of the inner preputial skin for ventral shaft coverage during circumcision may be all that is necessary to correct the defect.

Figure 72.4 Penoscrotal fusion.

Concealed penis

An otherwise normal penis that appears to be small is called a concealed, buried, or inconspicuous penis (Figure 72.5).[47] Measurements of stretched penile length and penile diameter are normal. Etiologic factors include a prominent prepubic fat pad, generalized obesity, and/or poor fixation of the subcutaneous tissue of the penis to Buck's fascia. Most commonly the patient is asymptomatic and spontaneous resolution can be anticipated with change in body habitus at puberty.[48,49] The extent of psychological distress in the untreated patient is unclear and when surgical intervention is elected results are poorly documented. Cromie et al[47] reported prolonged (median 5 years) follow-up, with durable improvement in most cases using a preputial unfurling and degloving procedure similar to techniques used to correct penoscrotal

Figure 72.5 Concealed penis in an obese prepubertal boy with normal stretched penile length.

fusion. The use of more complex procedures, such as prepubic liposuction or lipectomy, and closure with Z-plasties or skin flaps not only is rarely indicated but also may cause unnecessary scarring. However, Casale et al[50] reported follow-up from the parents of the patients perspective, at a minimum of 3 years, after the above-mentioned complex surgeries. The parents of infants and toddlers almost uniformly thought that surgical intervention alleviated negative concerns, addressed hygiene issues, and enhanced the appearance of the penis. Surgery was less successful in the adolescent population. Others reported early failure in as many as 35% of cases and long-term results are unknown.[48,51,52]

Micropenis

A penis that measures more than 2 or 2.5 standard deviations below the mean in stretched length for age but is otherwise normally formed is called a micropenis.[53,54] In newborns, a stretched length of <2.0 cm is considered abnormal. Normal development of the urethra and prepuce implies normal first trimester development, with impaired penile growth occurring in the second and third trimesters. Cryptorchidism may also be present. The most common etiology is gonadotropin deficiency with or without panhypopituitarism.[53] Other endocrine causes include growth hormone deficiency, testicular dysgenesis or regression and, rarely, 5α-reductase deficiency[55] or partial androgen insensitivity.[56] Micropenis may be present in gonadal determination disorders, such as Klinefelter's syndrome and XX sex reversal, and in Prader–Willi syndrome, Laurence–Moon–Biedl syndrome, Robinow's syndrome, and other rare syndromes, or it may be idiopathic.[53,54]

Evaluation of patients generally includes karyotype, determination of serum glucose, electrolytes, cortisol, and growth hormone levels, as well as thyroid function tests and pituitary imaging, as indicated.[53,54] Testicular function can be determined by measuring serum luteinizing hormone (LH), follicle-stimulating hormone (FSH), and testosterone before and after human chorionic gonadotropin (hCG) stimulation. The dose of hCG is 500–1500 international units (approx. 3000 IU/m^2) every other day for 5–7 days with serum testosterone measurements before and 24–48 hours after the last dose. Newborns can be evaluated for the normal spontaneous surge in serum gonadotropins and testosterone within the first few weeks of life; absence suggests a central (pituitary or hypothalamic) defect.

After diagnostic studies are complete, androgen stimulation therapy using intramuscular depot testosterone, 25 mg every 3–4 weeks for several months in infants, has been recommended to assess penile growth potential.[54,57] Unfortunately, response to testosterone does not always correlate with adequate penile size in adulthood, and may vary with the etiology of micropenis.[57,58] In this regard, patients with palpable testes[59] and significant response to gonadotropin-releasing hormone (GnRH) and hCG stimulation tests[60] appear more likely to have adequate long-term penile growth, although some do not.[58] Limited data suggest that treatment with dihydrotestosterone cream may be an effective alternative to parenteral testosterone, particularly in peripubertal males and in some patients who have failed testosterone therapy.[61] In patients with isolated growth hormone deficiency, growth hormone replacement appears to be sufficient for adequate penile growth.[62] Concerns that early androgen therapy might itself limit long-term penile growth potential are not supported by observations of males with early androgen excess syndromes.[63]

Until recently, routine gender reassignment was recommended for patients who show no penile growth response to testosterone.[53,54] However, the advisability of routine gender reassignment in genetic males with functioning testes has been questioned in other contexts,[20,32–35] and the long-term results of reassignment for micropenis are not known. Adequate sexual functioning and clear male gender identity in adulthood have been reported in some patients raised as males with persistent small penile size in adulthood,[64] but not in others.[58] Additional long-term follow-up data are critically needed to facilitate clinical decision making in these patients. Therefore, gender reassignment should be performed with caution and should be accompanied by expert ongoing patient and family counseling, including a discussion of the risks and benefits of penile reconstruction (see Chapter 71).

Priapism

Priapism is defined as a prolonged, frequently painful penile erection not sustained by sexual activity. The most common pediatric cause is homozygous sickle cell (SS) disease, but other possible etiologies include other hemoglobinopathies, leukemia, local malignancy, viral infections, pelvic infections or appendicitis, trauma, diabetes, amyloidosis, and Fabry's disease.[65,66] Low-flow priapism (ischemic) is usually present in affected boys with sickle cell disease, whereas a high-flow state (non-ischemic) is typically

present in trauma-induced priapism, but may rarely also be present in sicklers.[67,68] The incidence of priapism in males with sickle cell disease is 2–35%.[69–75] Stuttering episodes usually lasting less than 24 hours are common in both pediatric and adult patients. Initial episodes may occur in early childhood.

Priapism can be characterized by the site and degree of blood flow or stasis in the erectile tissues. Tumescence is usually limited to the corpora cavernosa but in some cases may also involve the corpus spongiosum, a situation termed tricorporeal priapism.[72] Spongiosal involvement, described in postpubertal individuals, is characterized by a firm, tender, engorged glans. Voiding difficulty may occur in some patients. Studies used to characterize degree of blood flow include analysis of aspirated penile blood, technetium 99m (^{99m}Tc) penile flow studies, and color Doppler ultrasonography. Low-flow priapism is characterized by acidosis, hypercarbia, and hypoxemia on penile blood gas analysis. The usefulness and reliability of penile nuclear scans and Doppler studies in children remain unclear. Miller et al[73] reported that nuclear scans did not predict outcome in a series of pediatric patients with sickle cell-associated priapism.

In the past, the initial treatment of patients with priapism due to sickle cell disease was hydration, analgesia, and transfusion to achieve a target hemoglobin S concentration of 30% or less.[69,70,73,76] However, in 2003 the Erectile Dysfunction Guideline Update Panel on the management of priapism[77] recommended that intracavernosal treatment should be administered concurrently with the above treatment if the priapism lasts longer than 4 hours. Intracavernosal therapy includes aspiration with irrigation and/or intracavernosal injection of a sympathomimetic drug. Prepubertal boys appear to respond more commonly to medical therapy than older patients.[71] Exchange transfusion has been associated with acute neurologic events characterized by reversible or irreversible cerebral ischemia, termed the ASPEN syndrome (association of sickle cell disease, priapism, exchange transfusion, and neurologic events).[78] Morbidity from this complication may be reduced by gradual or partial exchange transfusion, recognition of prodromal headache, and close monitoring.

With a total lack of response to medical and intracavernosal therapies, the next step should be surgical intervention.[69,73,75,77,79,80] The older view that surgical intervention in prepubertal patients with sickle cell priapism is unnecessary, if not contraindicated,[76] appears unjustified based on documented erectile dysfunction in boys following prolonged episodes of priapism.[79,81] For low-flow priapism, distal shunts (e.g. Winter, Ebbehoj and Al-Ghorab procedures) should be attempted prior to proximal shunts (e.g. Quackels and Grayhack procedures), because the distal shunts have fewer complications and are easier to perform.[77,80] These usually produce detumescence. Available long-term follow-up data suggest that potency is more commonly preserved in prepubertal patients, after episodes of shorter duration, and when successful intervention occurs early.[79,82,83]

For the patient with high-flow priapism, diagnosed by history, corporeal aspiration, and blood gas analysis, the Erectile Dysfunction Guideline Update Panel on the management of priapism[77] recommends observation, along with ice packs and site-specific compression, as the initial management. High-flow priapism is not associated with ischemia and will often resolve without treatment. Selective arterial embolization of the ruptured artery is the next step if observation fails or treatment is requested by the patient and/or family.[77,80]

A variety of other treatments have been suggested for patients with sickle cell disease and priapism; however, data are anecdotal or limited. α-Adrenergic agents such as etilefrine[84,85] have been given orally or intracavernosally with some success. Detumescence with hydroxyurea has been reported[86] but not confirmed in a large series. Other options include treatment with sildenafil,[87] GnRH analogues,[88] or antiandrogens,[89] but the latter two are not recommended in patients who have not achieved full sexual maturation and adult stature.[77]

Persistent, apparently painless penile erection has also been observed in newborns.[90] This condition resolves spontaneously in 2–6 days with no adverse sequelae. Associated, possibly contributing factors include polycythemia and birth trauma, although many reported cases are idiopathic.

Scrotal abnormalities

Two main types of scrotal pathology occur in the pediatric population: the commonly observed acute swelling of a normal scrotum (discussed under Inguinoscrotal disease) and the rare abnormalities of scrotal development.

Defects of number or position

Scrotal agenesis

Complete absence of the scrotum is an extremely rare anomaly, with only three reported cases in the

modern literature.[91–93] The penis was normal in all the cases, the perineum was smooth with a median raphe present, and both testes were superior to the expected scrotal site. Successful repair using preputial skin was performed.

Accessory scrotum

Ectopic scrotal tissue in addition to a normally developed scrotum is designated accessory scrotum or, in females, accessory labioscrotal fold. This anomaly is very rare, with 25 cases identified in the literature.[94,95] The accessory tissue is located on the perineum in the majority of cases and associated with a perineal lipoma and no other genitourinary anomalies. A case of isolated penile accessory scrotum has also been reported.[96] In the absence of a perineal lipoma, accessory perineal scrota are usually associated with other anomalies, including hypospadias, diphallia, defects of scrotal position, anorectal anomalies, and the VACTERL (vertebral, anal, cardiac, tracheoesophageal, renal, and limb anomalies) association.[97] Sule et al[94] hypothesize that, when present, the lipoma disrupts the continuity of the developing labioscrotal fold and the etiology in other cases is generalized perineal maldevelopment.

Ectopic scrotum

Ectopic positioning of the scrotum is usually unilateral, with the ectopic tissue usually suprainguinal but in some cases infrainguinal (femoral) or on the thigh.[98–100] The ipsilateral testis is usually present within the ectopic hemiscrotum, although associated cryptorchidism has been reported. Ipsilateral renal and ureteral anomalies are common, so patients should be evaluated for upper tract anomalies. Associated skeletal defects, penile torsion or chordee, hypospadias, and cleft palate have also been reported. Chowdhary et al[101] reported a case associated with a patent urachus. The etiology is uncertain, but may be related to a gubernacular defect failure of migration of the labioscrotal fold, or fetal deformation secondary to limb compression (foot). Treatment is generally simply achieved by flap scrotoplasty and orchidopexy.

Bifid scrotum

Incomplete fusion of the labioscrotal folds may produce a partial or complete separation of otherwise normally positioned hemiscrota in patients with severe hypospadias or chordee. The defect may be corrected by excision of the abnormal tissue and creation of a new scrotal raphe with reapproximation of the hemiscrota in the midline.

Penoscrotal transposition

In cases of penoscrotal transposition, part or all of the scrotum is located superior to the penile shaft. The spectrum of findings ranges from a normal-sized penis with confluent scrotal tissue both anterior and posterior (shawl or doughnut scrotum) to complete transposition of a rudimentary penis to the perineum behind an intact scrotum, a phenotype similar to that of penile agenesis.[102] The posterior aspect of the scrotum may be bifid and/or hypoplastic, and hypospadias and chordee are frequently present (Figure 72.6). However, multiple other anomalies of diverse organ systems have also been identified. These include renal, central nervous system, developmental, gastrointestinal, respiratory, limb, vertebral, cardiovascular, facial, and ocular anomalies.[102] Three types of chromosomal defect have been identified: trisomies 8 and 18, and distal deletions of the long arm of chromosome 13.[103] Correction of the defect may be performed during or subsequent to hypospadias repair by mobilization of the anteriorly placed scrotal skin with ventral transposition and closure, as described by Glenn and Anderson[104] (see Chapter 71). In some cases ventral penile tethering may occur postoperatively and may be corrected by interposition of thigh-based neurovascular flaps.[105]

Median raphe cysts

Midline cysts may arise anywhere along the median raphe between the urethral meatus and anus.[106–108] Their origin is believed to be epithelial or endothelial

Figure 72.6 Partial penoscrotal transposition and bifid scrotum in a patient with proximal hypospadias.

rests trapped in an aberrant subcutaneous location during developmental approximation of the urethral and genital folds. They may be large and elongated and appear translucent. Histologically, they are lined with cuboidal or squamous epithelium and contain sebaceous material. Rarely, the proximal portion of the cyst may traverse the urogenital diaphragm and extend into the pelvis. Magnetic resonance imaging (MRI) may be useful to define the extent of the lesion preoperatively if pelvic extension appears likely. Treatment is complete excision of the cysts with midline closure.

Inguinoscrotal disease

Varicocele

Population studies have confirmed the observation that a varicocele first becomes clinically evident between the ages of 10 and 15 years[109] and once a varicocele is present it will normally persist for the remainder of that individual's life.[110] The varicocele which has its origin in adolescence may be a major cause of infertility in adults. However, if one waits until adulthood to treat varicocele-induced infertility, success is unlikely for the majority of men.[111] Because of this experience, recent efforts have focused on identifying teenagers with an asymptomatic varicocele in an attempt to identify individuals at risk, intervene earlier, and hopefully improve results. Although this approach seems reasonable, the problem for the clinician has been establishing uniform criteria for treatment. The observation that a varicocele occurs in 15% of men adds to the difficulties in deciding when treatment is indicated. Do we treat all men with a varicocele or just selected ones?

The vast majority of teenagers with a varicocele are discovered during a routine school physical, are asymptomatic, and are unaware of the presence of the varicocele. As a consequence most of the teenagers identified with a varicocele have a grade II (mass or veins 1–2 cm in diameter) or grade III (large mass or veins easily visible and >2 cm in diameter) varicocele. A child with a small varicocele (veins ≤ 1 cm in diameter) can only be detected by a skilled examiner, and most will escape early detection. No investigators have reported using color Doppler ultrasound to detect a subclinical varicocele in a teenager and therefore this entity appears to have no clinical significance in the teenage population at the current time.

Since most teenagers with a varicocele are detected during a routine physical examination by a primary care physician, it is reasonable to assume that a teenager with a large varicocele is more likely to be diagnosed than one with a small varicocele. Dubin and Amelar[112] concluded that the size of a varicocele was not a significant fertility variable. However, Fariss et al[113] demonstrated that in adult men found to have a varicocele on routine physical examination there was a greater chance of a man with a large varicocele having a sperm count <20 million/ml than a man with a small varicocele. Several other studies have reported that in men with a large varicocele there is greater impairment in semen parameters than in men with a small varicocele.[114–116] Steeno et al[109] noted that, with increasing varicocele size, there was progressively more volume loss of the testis ipsilateral to the varicocele. Other studies[117] have also demonstrated lower testicular volumes in men with a large varicocele than in those with a small one. This loss of testicular volume may be significant because the seminiferous tubules constitute >50% of the testicular mass, and in adult men total sperm count correlates with testicular volume.[118,119] Therefore, it is reasonable to conclude that an individual with a large varicocele may be at greater risk for testicular injury than someone with a small varicocele.[120]

The mechanism by which a varicocele induces testicular injury is still unresolved, although many theories have been proposed. Investigators have noted that a varicocele, both clinically and experimentally, results in an increase in scrotal and testicular temperature.[121] An increase in testicular temperature has been shown to be toxic to the testis in humans as well as other mammals with scrotal testes.[122–124] Aggar[125] reported that following varicocele correction there was a good correlation between the fall in left testicular temperature and the improvement in spermatogenesis. Kass and Salisz[126] measured scrotal temperatures in adolescents with grade II and III varicoceles and reported that there was a significant bilateral elevation in scrotal temperature when compared with control subjects without a varicocele. They also noted that the higher the left scrotal temperature the greater the volume loss of the left testis. Following successful varicocele correction, scrotal temperature normalized.

In an infertile adult male with a unilateral left varicocele, abnormal testicular histology can be demonstrated in both testes and involves all cell types, although the changes are typically more pronounced in the left testis (Figure 72.7).[127–129] Similar histopathology has been demonstrated bilaterally in the adolescent with a unilateral varicocele, but the

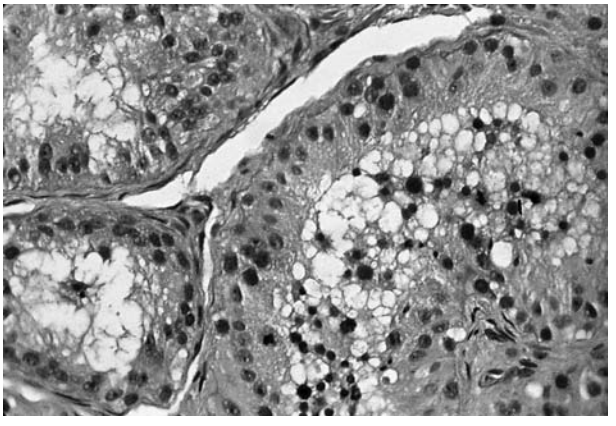

Figure 72.7 Testicular histology in a patient with a varicocele showing Sertoli only tubules and severe maturation arrest. Only 25% of tubules were normal in this patient (× 250).

abnormalities are less severe.[130,131] It is important to note that, while the pathologic changes in the seminiferous tubules, blood vessels, and Sertoli cells are present to varying degrees in infertile men with a varicocele, the relative severity of the abnormality in these cell types is not the key prognostic variable. Investigators have reported that it is the severity of the Leydig cell pathology that is most significant in determining the potential for reversibility of the varicocele-induced testicular injury.[132] Individuals with Leydig cell hyperplasia have a very poor prognosis, whereas those with Leydig cell atrophy have a better prognosis for fertility following varicocele correction. The prognosis for return of fertility is independent of the degree of tubular pathology and ultimately it is the degree of the pathologic changes in the Leydig–Sertoli cell interrelationship that ultimately decides whether surgery will be successful with regard to fertility.[133] Hadziselimovic et al[134] reported that Leydig cell atrophy was the predominant pathologic finding on testicular biopsy in teenagers undergoing varicocele surgery (74%) when compared with adults in whom Leydig cell hyperplasia was more common, with atrophy being found in only 22%. These various histologic studies taken as a whole suggest that varicocele-induced histologic abnormalities occur in adolescents and are progressive. The pathology is potentially reversible early on but once Leydig cell hyperplasia is present surgical correction of the varicocele will be unlikely to have beneficial effects.

Varicoceles also induce endocrinologic abnormalities that parallel the histopathology. Weiss et al[135] measured the in-vitro synthesis of testosterone from testicular biopsy material and noted that there was a significant reduction in testosterone formation in 90% of infertile men with a varicocele. In these same individuals peripheral levels of testosterone and LH were normal. Other investigators have also reported significant varicocele-induced Leydig cell dysfunction and noted that the abnormalities are progressive.[136–138]

An exaggerated gonadotropin response to the administration of GnRH has been demonstrated in infertile men with a varicocele and is thought to be the result of a primary testicular injury. The excessive release of LH following GnRH stimulation is an indicator of Leydig cell dysfunction and the exaggerated FSH response an indicator of an abnormality of the seminiferous tubules. Nagao et al[139] measured the response to GnRH stimulation and noted that semen and hormonal abnormalities can be observed in both fertile and infertile men with a varicocele, suggesting that there may be some degree of testicular dysfunction in all men with a varicocele, regardless of their fertility status. They suggested that perhaps with increasing age the varicocele-induced testicular injury could become clinically evident in more men. Several investigators[140–144] demonstrated that the excessive gonadotropin response to GnRH stimulation in infertile men was reversible after varicocele correction only in those individuals whose spermiograms also improved. Individuals who did not demonstrate an improved postoperative gonadotropin response pattern did not show any improvement in their spermiogram.

The gonadotropin response to GnRH stimulation has been shown to be a useful diagnostic tool for evaluating testicular function in teenagers.[145,146] Kass et al[147] measured the gonadotropin response pattern to GnRH stimulation in adolescent males with a varicocele and compared it with a group of normal teenagers without a varicocele. They noted that an abnormal gonadotropin response was present in almost one-third of teenagers with a varicocele, and that this test may be useful in identifying those varicocele patients with early evidence of testicular injury.

Barwell[148] was the first to report volume loss of the testis ipsilateral to a varicocele in a teenager, and noted the testis 'became harder and regained some of its dimensions' following surgical correction. In adult men with infertility, both testes tend to be smaller than in aged-matched control groups without a varicocele. Kass and Belman[149] performed varicocele ligation on adolescent males with grade II–III left-sided varicocele and volume loss of the left testis. Significant catch-up growth of the left testis was noted in 80% of

Figure 72.8 Left testicular volume loss in a patient with a left varicocele.

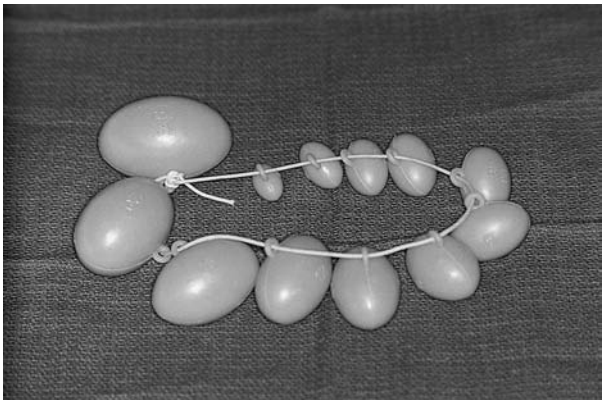

Figure 72.9 Prader orchiometer.

patients. Subsequent studies have confirmed their findings and indicate that a varicocele can be responsible for testicular growth retardation, and early successful correction can reverse this process.[150–153] In the majority of adolescents with a varicocele, testicular volume loss is the most common indication of testicular injury and therefore the most significant indication for intervention. Normal testicular size correlates with stage of sexual maturity.[154,155] Testicular volume progressively increases from approximately 4 to 25 ml during pubertal development, making it difficult to calculate a normal testis volume in any individual before adulthood. Most investigators have used the right testis as the 'normal control'. If the left testis is 3 ml or more smaller than the right, then significant testicular volume loss is considered to be present (Figure 72.8). Accurate testicular volume measurements are possible with a standard Prader orchiometer (Figure 72.9) and correlate well with volume measurement by ultrasonography; however, the degree of correlation is dependent on the investigator's clinical experience.[156]

In adults with a varicocele, the assessment of a semen sample is a reasonable first step in the evaluation process since there are established normal parameters. Unfortunately, in adolescents it is often difficult to obtain such samples, and even when available, normal adult values for semen volume, spermatozoa concentration, and morphology are not achieved until 2–3 years after the onset of puberty.[157] It is important to remember that a single normal semen analysis does not predict future normality, since the effect of a varicocele may increase with time.[127] Although semen analysis is not practical in the adolescent population, at least one report has shown improvement in semen parameters after adolescent varicocele repair.[158] It is recommended that every adult with a palpable varicocele should have a semen analysis on an annual basis until the completion of his family in order to ensure that abnormalities do not develop.

Current data indicate that it is important to identify and evaluate all teenagers with a varicocele. Certainly no one can predict with absolute certainty whether any adolescent with a varicocele will be fertile or infertile; however, based on existing information it can be expected that many will develop a fertility problem that becomes progressive if left untreated.[159–161] Individuals with volume loss of the testis ipsilateral to the varicocele appear to have a greater likelihood of having a normal semen analysis if treated as a teenager than if left untreated.[162–164] Similarly, individuals with large varicoceles may be at future risk for developing testicular volume loss and abnormal semen parameters. Although there are concerns that an abnormal GnRH stimulation test may be associated with similar long-term risks,[165] that hypothesis is not generally accepted as an indicator for intervention when other parameters are normal. Similarly, it is unclear whether intervention in otherwise normal individuals with bilaterally palpable varicoceles or scrotal discomfort is reasonable, and should be considered routine. Persistently abnormal semen parameters in older teenagers and adults are of significant concern and should be considered an indication for intervention.

Multiple techniques have been proposed for correction of a varicocele in a teenager.[166,167] Selective transvenous embolization of the internal spermatic vein.[168–171] is a complex, invasive procedure with a significant recurrence and non-occlusion rate. Laparoscopic venous ligation[172–176] requires intubation and

bladder catheterization, and has the rare potential for significant intra-abdominal complications. Conventional inguinal[177] and retroperitoneal approaches with attempted preservation of the testicular artery are simple and relatively complication-free procedures but have an unacceptably high risk for failure.[178] Current data suggest that the above techniques are not the best choice for varicocele correction in teenagers. The Palomo technique[179] with mass ligation of the internal spermatic vessels,[177,178,180–183] or the inguinal[184] or subinguinal approach[185] with microscopic ligation[186–188] of all venous channels are the procedures with the highest success rate and fewest complications, and are the procedures of choice for varicocele correction in teenagers. However, secondary hydrocele is common with mass ligation of the internal spermatic vessels and the potential risk for testicular atrophy, should vasectomy be carried out in the future, must be considered. However, preservation of a single lymphatic vessel may prevent hydrocele.

Acute scrotal disease

Testicular torsion must be considered in any patient who complains of acute scrotal pain and swelling. Torsion of the testis is a surgical emergency because the likelihood of testicular salvage decreases as the duration of torsion increases. Conditions that may mimic testicular torsion, such as torsion of a testicular or epididymal appendage, epididymitis, trauma, hernia, hydrocele, varicocele, and Schönlein–Henoch purpura, generally do not require immediate surgical intervention. The cause of an acute scrotum can usually be established based on a careful history, a thorough physical examination, and appropriate diagnostic tests. The onset, character, and severity of symptoms must be determined. The physical examination includes inspection and palpation of the abdomen, testis, epididymis, scrotum, and inguinal region. Urinalysis should always be performed, but scrotal imaging is necessary only when the diagnosis remains unclear.

History

The history and physical examination can significantly narrow the differential diagnosis of an acute scrotum. Testicular torsion is most common in neonates and postpubertal boys, although it can occur in males of any age. Schönlein–Henoch purpura and torsion of a testicular appendage typically occur in prepubertal boys, whereas epididymitis most often develops in postpubertal boys.

Testicular torsion usually begins abruptly in the early morning and the pain is often severe from the onset. Moderate pain developing gradually over several hours or days is more suggestive of epididymitis or appendiceal torsion.

A history of scrotal trauma is common and does not exclude the diagnosis of testicular torsion. Minor scrotal trauma incurred during sports activities or rough, boisterous play typically causes severe pain of short duration. Pain that persists for more than 1 hour after scrotal trauma is not normal and merits investigation to rule out testicular rupture or acute torsion. Pain that resolves promptly after scrotal trauma only to recur gradually a few days later suggests traumatic epididymitis.

Many patients with testis torsion describe previous episodes of similar pain that lasted for only a short time and resolved spontaneously. Acute on-and-off pain associated with or without scrotal swelling suggests intermittent torsion with spontaneous detorsion. Voiding dysfunction, congenital genitourinary anomalies, and urethral instrumentation can predispose patients to bacterial UTIs and secondary epididymitis.

Physical examination

A general abdominal examination should be performed, with particular attention given to flank tenderness and bladder distention. The inguinal regions should be examined for obvious hernias and any swelling or erythema. The spermatic cord in the groin may be tender in a patient with epididymitis but typically is not tender in a patient with acute testicular torsion.

The scrotum should be assessed for discrepancies in size, degree of swelling, presence and location of erythema, thickening of the skin, and position of the testis. Unilateral swelling without skin changes suggests the presence of a hernia or hydrocele. A high-riding testis with an abnormal (transverse) lie may suggest torsion (Figure 72.10), but this diagnosis is unlikely if the pain has been present for over 12 hours and the scrotum has a normal appearance. In both epididymitis and testicular torsion, the affected hemiscrotum typically displays significant erythema and swelling after 24 hours.

The cremasteric reflex should always be assessed. One study[189] found that the cremasteric reflex was intact in 100% of boys aged 30 months to 12 years but was not consistently normal in infants and teenagers. The cremasteric reflex is rarely intact in

Figure 72.10 High-riding, swollen left testis in a patient with acute spermatic cord torsion.

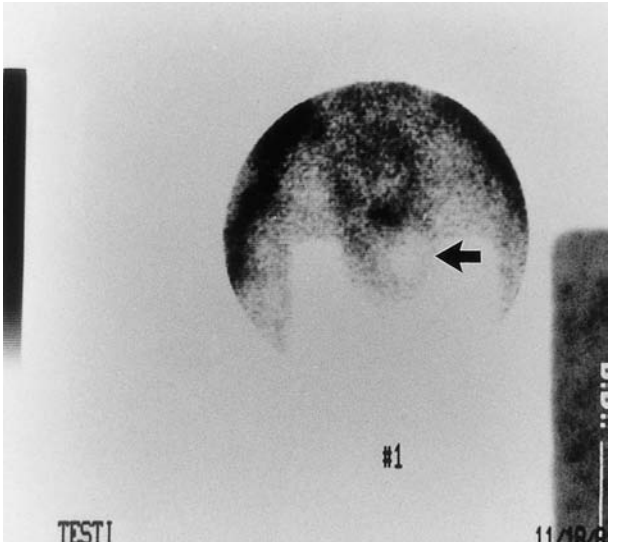

Figure 72.11 Early testicular torsion: nuclear testicular scan showing absence of tracer (arrow) in the left testis.

patients with testicular torsion but is usually present in patients with torsion of a testicular or epididymal appendage.[190]

In early torsion, the entire testis is swollen and tender, and is larger than the unaffected testis. Tenderness limited to the upper pole suggests torsion of a testicular appendage, especially when a hard, tender nodule is palpable in this region. A small bluish discoloration representing the necrotic torsed appendage, known as the 'blue dot sign,' may be visible through the skin at the upper pole. This sign is virtually pathognomonic for appendiceal torsion when tenderness is also present. In early epididymitis, the epididymis exhibits tenderness and induration, but the testis itself is not tender. Swelling to the degree that the epididymis is no longer palpable can indicate testis torsion if the symptoms have been present for only a few hours. With both appendiceal torsion and epididymitis, loss of testicular landmarks occurs later in the clinical course. The testis may be elevated to elicit Prehn's sign. Lack of pain relief (negative sign) may contribute to the diagnosis of testicular torsion. If torsion is suspected, manual detorsion can be attempted by rotating the testis away from the midline.

Diagnostic studies

Urinalysis is performed to rule out UTI in any patient with an acute scrotum. Pyuria with or without bacteruria suggests infection and is consistent with epididymitis.

Historically, it was thought that no imaging studies were useful in confirming the cause of an acute scrotum. Immediate surgical exploration was thus the standard approach when torsion was suspected. However, studies conducted in the past few years have shown that only 16–42% of boys with an acute scrotum have testicular torsion.[191–194] Therefore, routine exploration of all children is not reasonable if tests are available to improve diagnostic accuracy.

Initially, Doppler stethoscopes and conventional gray-scale ultrasonography were used to diagnose or exclude the presence of torsion, but these tests lack sensitivity and specificity.[195] Nuclear testicular flow studies are helpful, and when performed by experienced personnel can reliably identify children with torsion (Figure 72.11), epididymitis (Figure 72.12), and late torsion (Figure 72.13). However, since it is strictly a blood-flow study a testicular scan is not helpful when a hydrocele or hematoma is present because

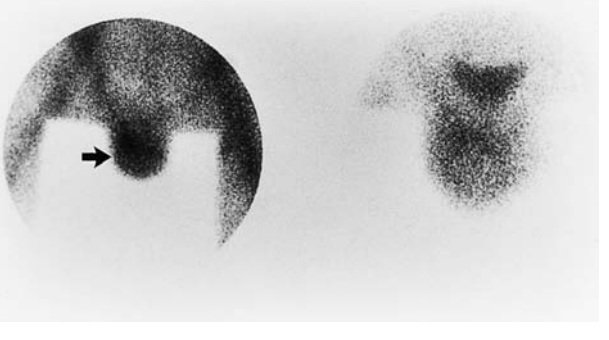

Figure 72.12 Epididymitis: nuclear testicular scan showing flow in both testes and increased activity in the right hemiscrotum (arrow).

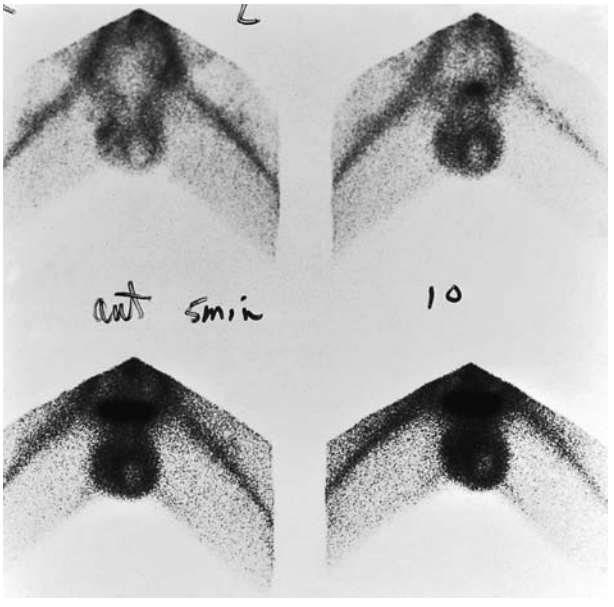

Figure 72.13 Late testicular torsion: nuclear testicular scan showing a 'halo' sign, or increased flow around the avascular left testis.

these conditions may mimic the findings of torsion. In addition, it is of critical importance to localize the exact position of the testis; otherwise, no reliable test is possible. In addition, most centers do not have personnel experienced in the performance or interpretation of nuclear medicine scrotal scans.

Color Doppler sonography has become the most popular diagnostic modality to evaluate a child with an acute scrotum because it is non-invasive and has a diagnostic accuracy at least equal to that of nuclear scanning. It can semiquantitatively characterize blood flow, distinguish intratesticular and scrotal wall flow, and can also be used to assess other pathologic conditions involving the scrotum (Figures 72.14–72.16).[196–198] Proper technique is essential. When color Doppler examinations are not performed correctly, false-positive or false-negative studies may occur. Certain caveats are important to remember. It may not be possible to demonstrate a Doppler signal in the small testes of very young boys. Just seeing color dots does not mean that flow is present; one must see a wave form within the substance of the testis. Reduced flow in a painful testis relative to the normal testis may indicate torsion, and exploration is indicated.

Spermatic cord torsion

The suggested protocol for the evaluation of a child with an acute scrotum (Figure 72.17) states that when the history and physical examination strongly

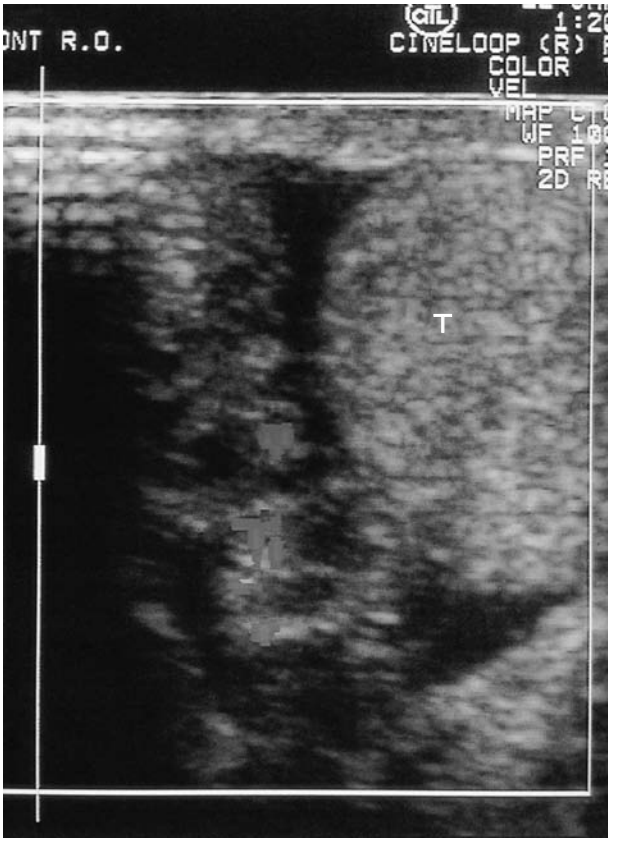

Figure 72.14 Testicular torsion: color Doppler ultrasound showing lack of flow in the testis (T).

suggest that testicular torsion is present and the duration of the pain is less than 12 hours, urgent surgical intervention is indicated.[199] Imaging studies may delay treatment and thereby jeopardize testicular survival. When pain has been present for more than 12 hours or the diagnosis is unclear, color Doppler ultrasound examination can be helpful in making clinical

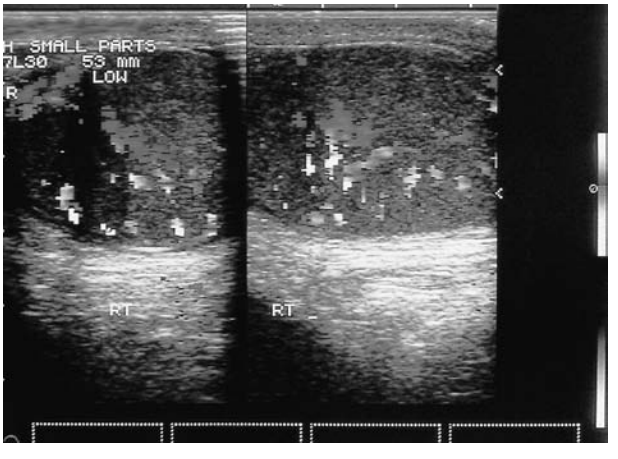

Figure 72.15 Orchitis: color Doppler ultrasound showing increased flow to the right testis.

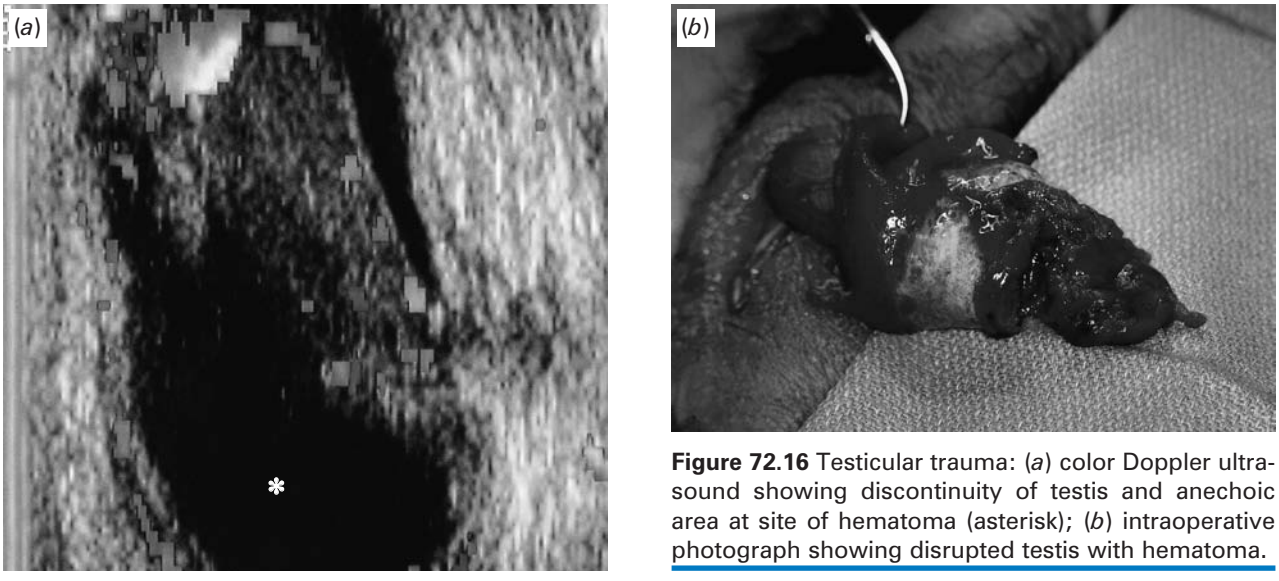

Figure 72.16 Testicular trauma: (*a*) color Doppler ultrasound showing discontinuity of testis and anechoic area at site of hematoma (asterisk); (*b*) intraoperative photograph showing disrupted testis with hematoma.

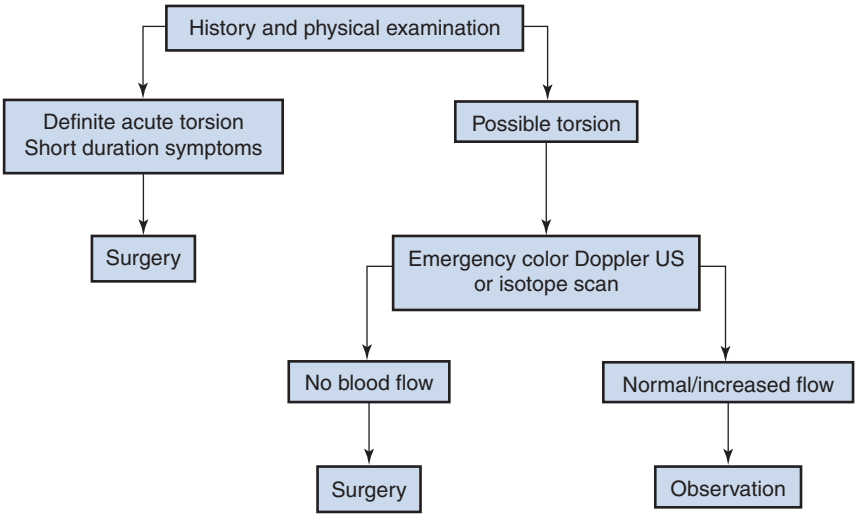

Figure 72.17 Algorithm for evaluation and treatment of patients with acute scrotal pain. (US = ultrasonography.)

decisions. It is important to remember that most patients with an acute scrotum do not have testicular torsion.

The 'bell clapper' deformity is the underlying cause of testicular torsion in older children. In this deformity, the testicle lacks a normal attachment to the tunica vaginalis and therefore hangs freely. As a result, the spermatic cord can twist within the tunica vaginalis (intravaginal torsion).

Surgery is performed to correct torsion in the affected testis and to anchor the other testis to prevent future torsion. Surgical exploration can usually be accomplished through a single, small, midline incision in the scrotal raphe. Testes that are unequivocally necrotic should be removed. Viable testes should be fixed to the scrotal wall with multiple non-absorbable sutures.

Testicular torsion can also occur perinatally before the entire testis complex has fused to the scrotum. In this type of torsion the testis, spermatic cord, and tunica vaginalis twist en bloc (extravaginal torsion) (Figure 72.18). Clinically, extravaginal torsion generally appears as a hard asymptomatic intrascrotal swelling in the newborn. Erythema or a bluish discoloration of the scrotum is also frequently seen and may be confused with a hydrocele.

The management of perinatal torsion remains controversial. Some surgeons advocate a non-operative approach because of the poor potential for testicular salvage. Others argue that leaving a neonatal testis in place may have adverse effects on the contralateral testis and note that cases of bilateral neonatal torsion have been reported.[200] Also controversial is the question as

Figure 72.18 Extravaginal torsion (twisted cord – arrow).

to whether or not the remaining solitary testis should be fixed in place, although risk of torsion of that testis is no greater than for the general (adult) population.

Torsion of an appendix of the testis or epididymis

The appendix testis, a müllerian duct remnant located at the superior pole of the testicle, is the most common appendage to undergo torsion (Figure 72.19). The epididymal appendix, located on the head of the epididymis, is a wolffian duct remnant and may also become twisted. Torsion of either appendage produces pain similar to that experienced with testicular torsion, but the onset is more gradual. The cremasteric reflex is not lost with torsion of an appendage. Color Doppler ultrasonography often demonstrates increased blood flow that may be indistinguishable from epididymitis. Occasionally a hypoechoic mass near the upper pole of the testis, the torsed appendage, may be visualized.

Torsion of a testicular appendage may be misinterpreted as epididymitis. However, if the urinalysis is normal, no antibiotic therapy is required. Management entails symptomatic treatment to minimize inflammation and edema. Normal activity may both worsen and prolong the symptoms. Non-steroidal anti-inflammatory drugs (NSAIDs) may offer symptomatic relief to some patients. The inflammation usually resolves within 1 week, although the testicular examination may not be completely normal for several weeks, with induration in the region of the head of the epididymis persisting for that interval.

Figure 72.19 Torsion of appendix testis (arrow). Note accompanying enlargement and hyperemia of the epididymis.

Epididymitis or orchitis

Epididymitis in adolescents and young adults is often unrelated to sexual activity and does not present with a UTI. In prepubertal boys, however, bacterial epididymitis is often associated with a urinary tract anomaly.[201] Any episode of epididymitis and UTI should be investigated with a renal/bladder sonogram and a voiding cystourethrogram (VCUG) to rule out structural problems. The cause of epididymitis in the majority of young men can often not be determined, however.

Treatment includes empiric antibiotic therapy until the results of a urine culture are known. If the culture is negative, the symptoms are most likely to be due to abacterial chemical epididymitis caused by the retrograde reflux of urine into the vas deferens. Bedrest and scrotal elevation are often helpful. Symptoms may be alleviated with NSAIDs and analgesics. As with appendiceal torsion, the pain and swelling generally resolve within 1 week. Resolution of epididymal induration may require several weeks.

Scrotal trauma

Severe testicular injury is uncommon and usually results from either a direct blow to the scrotum or a straddle injury. Damage generally occurs when the testis is forcefully compressed against the pubic bones. A spectrum of injuries may occur. Traumatic

epididymitis is a non-infectious inflammatory condition that usually occurs within a few days after a blow to the testis.[202] Treatment is similar to that of non-traumatic abacterial epididymitis. Scrotal trauma can also result in intratesticular hematoma, hematocele, or laceration of the tunica albuginea (testicular rupture). Color Doppler ultrasonography is the imaging technique of choice (see Figure 72.16). Testicular rupture is a surgical emergency requiring debridement of devascularized tissue and closure of the tunica albuginea. Isolated hematomas and hematoceles are managed on an individual basis.

Lacerations of the scrotum itself are a fairly common occurrence in active boys, usually the consequence of bicycle accidents or getting caught on a fence. Most are superficial and do not involve the tunica vaginalis, requiring only minor suturing with sedation and local anesthesia. Deeper injuries may require a trip to the operating room.

Other acute scrotal disease

Acute idiopathic scrotal edema is another cause of an acute scrotum (Figure 72.20). This condition is characterized by the rapid onset of significant edema without tenderness. Erythema may be present. The patient is usually afebrile and all diagnostic tests are negative. The etiology of this condition remains unclear. Treatment consists of bedrest and scrotal elevation. Analgesics are rarely needed.

Schönlein–Henoch purpura, a systemic vasculitic syndrome of uncertain etiology, is characterized by non-thrombocytopenic purpura, arthralgia, renal disease, abdominal pain, gastrointestinal bleeding and, occasionally, scrotal pain and swelling.[203] The onset can be acute or insidious. Hematuria may be present. The syndrome has no specific treatment.

The overriding need in the child with scrotal edema is to rule out testicular pathology. Color Doppler sonography may be helpful, but it may also be possible to make this determination clinically. If the testes can be manipulated gently into the superficial inguinal pouches and palpated, their non-involvement in the inflammatory process may be proven and no further diagnostic studies need be carried out.

Hernia and hydrocele

Inguinal hernia and hydrocele in childhood is most commonly due to patency of the processus vaginalis, an extension of peritoneum that forms in the first trimester in proximity to the gubernaculum of both sexes.[204] In males, the processus vaginalis migrates distally through the inguinal canal with the masculinized gubernaculum,

Figure 72.20 Idiopathic scrotal edema.

facilitates descent of the testis, persists distally as the tunica vaginalis, and normally becomes obliterated proximally. In females, the processus vaginalis develops but does not enlarge substantially. In both sexes, failure of closure of the processus creates a potential site for clinical hernia formation, characterized by passage of fluid or intra-abdominal viscera into the persisting sac.

The timing of closure of the processus vaginalis and its relationship to clinical hernia formation can be inferred from data obtained at autopsy, inguinal exploration, intraoperative laparoscopy, and studies of patients requiring ventriculoperitoneal shunts. These studies suggest that the processus is open in more than 80% of individuals at birth, and closure is most common in the first year of life but may occur much later. Patency persists in 15–30% of adults.[205,206] However, clinical hernias develop in fewer than 30% of newborns and 10% of 1 year olds after placement of a ventriculoperitoneal shunt.[207] Similarly, contralateral patency of the processus vaginalis has been reported to be as high as 40–50% of children with unilateral inguinal hernias.[208] However,

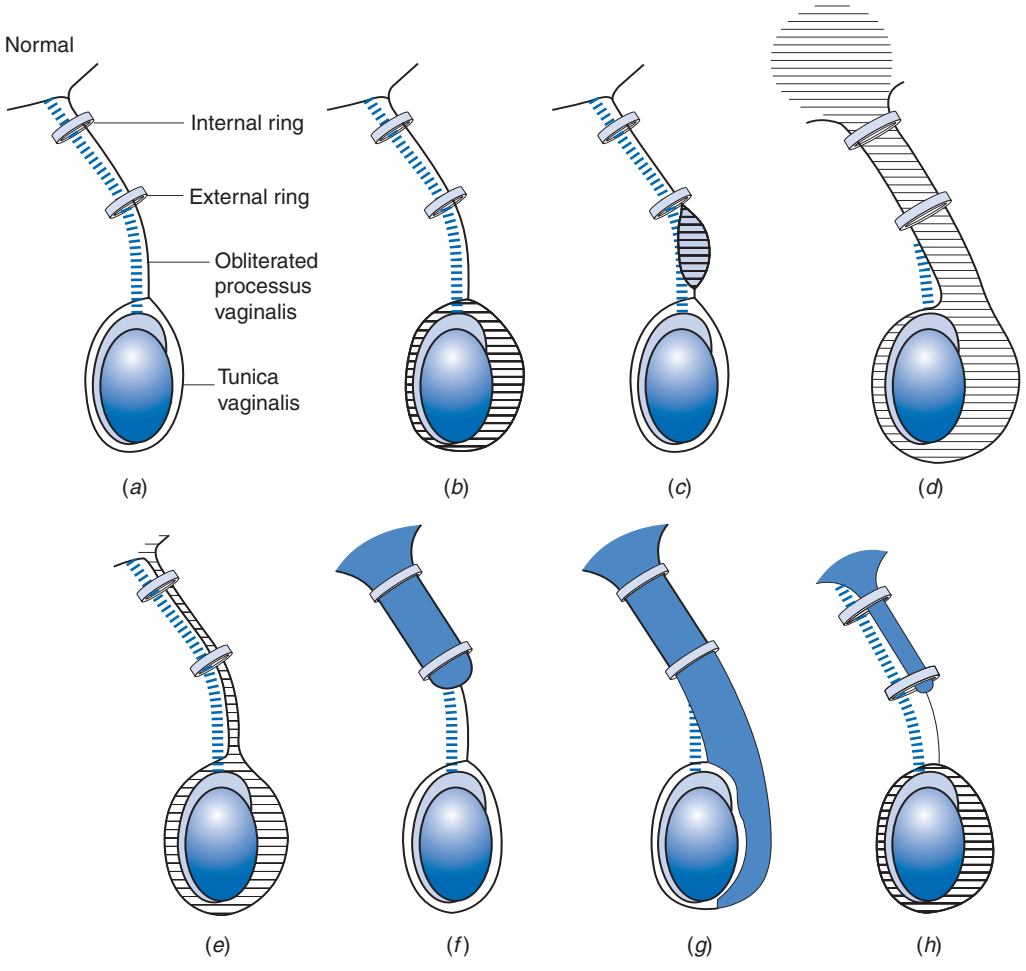

Figure 72.21 Possible findings in patients with hernia and/or hydrocele. Hatched black areas represent fluid and dark blue areas represent intra-abdominal contents: (*a*) normal findings; (*b*) scrotal hydrocele without hernia; (*c*) hydrocele of the cord; (*d*) abdominoscrotal hydrocele; (*e*) communicating hydrocele; (*f*) inguinal hernia; (*g*) inguinoscrotal hernia; (*h*) inguinal hernia and scrotal hydrocele.

only 7% of children who undergo unilateral hernia repair subsequently develop a clinical hernia on the opposite side.[209] Therefore, not all potential hernias manifest themselves clinically, even in the presence of increased intra-abdominal pressure.

The incidence of pediatric hernia is 10–20 per 1000 and is greater in premature infants (7%), in males (85% of total), and in the first 6 months of life (30% of total).[206,210] Clinical hernias are more frequent on the right side and are bilateral in approximately 10% of both male and female children. Incarceration occurs most frequently in the first year of life. Patients may present with an inguinal bulge and/or enlarged scrotum or labium, irritability, vomiting, and obstipation. In the absence of incarceration, a hernia may be diagnosed during the Valsalva maneuver (crying or blowing up a balloon) or by observation of inguinal asymmetry and palpable thickening of the spermatic cord distal to the external ring. These findings may be facilitated by examining the patient in the upright position. The spectrum of anatomic findings is shown in Figure 72.21.

Surgical repair is indicated when the clinical history and physical findings suggest visceral involvement or when fluctuation in size is observed. Prompt repair is also advised in infancy to reduce the risk of incarceration. If an incarcerated hernia requires reduction, surgical repair should be urgent, or emergent if peritoneal signs suggest that bowel strangulation is present. The question of contralateral inguinal exploration at the time of repair of the symptomatic hernia is controversial. Some surgeons base their decision on laparoscopic evaluation of the contralateral internal ring.[208] However, while this may reduce the incidence of routine inguinal exploration, the data cited above suggest that the majority of patent processes

vaginales will remain asymptomatic. Routine contralateral exploration may be reasonably limited to situations associated with a higher risk for metachronous hernia and/or morbidity, such as age <1 year, history of prematurity, and increased abdominal pressure from shunts, dialysis, or ascites.

Principles of repair include a small, transverse incision over the inguinal canal, isolation of the sac with minimal handling of cord structures, reduction of any abdominal viscera, and high ligation of the hernia sac. Formal repair of the internal ring or floor of the canal is rarely needed in children. Generous windowing of an undrained hydrocele, which may be loculated, should be performed after transection and ligation of the hernia sac. The testis should be replaced in its normal position in the scrotum.

Scrotal hydroceles without associated patency of the processus vaginalis are common in newborns and may be quite large. Diagnosis is made by transillumination, and the inability to reduce the mass, forcing the fluid back into the peritoneal cavity, rules out hernia. Most resolve spontaneously and treatment is not recommended.

Persistence of a simple scrotal hydrocele beyond 18 months of age may be an indication for surgical correction. However, there is no evidence that a simple hydrocele risks testicular damage and treatment is generally cosmetic, although some boys will complain of discomfort if the mass is particularly large.

Fluid may also be trapped within the tunica vaginalis of the spermatic cord. The diagnosis is made by identifying a non-decompressible, transilluminatable mass above and separate from the testis.

Treatment of simple hydroceles or hydroceles of the cord is similar to that in adults; however, an inguinal approach is recommended to rule out associated patency of the proximal tunica vaginalis at the level of the internal inguinal ring. Excision or plication of the enlarged tunica vaginalis is generally effective.[211]

Finally, hydroceles may occur acutely following minor scrotal trauma or a viral illness associated with coughing or vomiting. The acute rise in intra-abdominal pressure associated with coughing or vomiting may force peritoneal fluid through a minimally patent processus vaginalis. Many of these will resolve spontaneously and a period of observation for several weeks before recommending surgical intervention is advised.

Many unusual structures have been observed within hernia sacs:[212]

- abscess
- adrenal hemorrhage
- adrenal tissue, adrenal tumor
- appendix
- bladder
- cystic dysplasia of testis
- dermoid cyst
- ectopic renal tissue
- ectopic testis
- epidermoid cyst of testis
- epididymal cysts, nodules, structural anomalies, tumors
- fat necrosis of scrotum
- fibrous adnexal pseudotumor
- free nodules, calculi
- funniculitis (thrombosis of pampiniform plexus)
- gonad or genital structure of opposite sex
- granulomas (talc, etc.)
- glaucomatous disease (acidosis, etc.)
- hemangioma
- intussuscepted processus vaginalis
- lymphangioma
- Meckel's diverticulum
- meconium granuloma
- mesenchymoma
- neuroblastoma
- parasitic disease
- paratesticular cyst
- paratesticular rhabdomyosarcoma
- pedunculated body
- peritonitis pseudotorsion
- pneumoscrotum
- polyarteritis nodosa
- polyorchidism
- Richter's hernia
- scrotal calculi
- spermatic cord tumors
- spermatocele
- splenogonadal fusion
- testicular infarct
- tunica albuginea cyst
- tunica vaginalis tumor
- ureter
- uterus
- vas deferens agenesis
- vasitis nodosa
- venous thrombosis
- Wilms' tumor
- xanthogranuloma (juvenile).

Preoperative clinical findings will suggest the presence of some of these structures, such as spermatic cord tumors. Previously unsuspected discoveries in the inguinal canal become clinically significant in the

context of hernia repair if they suggest an additional diagnosis that requires treatment, are confused with normal tissue or are removed inadvertently, producing morbidity. Additional diagnoses of significance include persistent müllerian duct syndrome (usually associated with cryptorchidism), intersex abnormalities in phenotypic females, and testicular, vasal, or epididymal anomalies (see below). Since androgen insensitivity syndrome is present in about 1% of girls undergoing hernia repair,[213] routine exposure of the ovary and/or vaginal examination under anesthesia is warranted in these cases.

Incompletely developed portions of vas or epididymis have been identified by microscopic analysis of excised hernia sac tissue in 1.5–4% of cases and may cause concern of vasal injury. These can be differentiated from normal vas and epididymis by their small mean diameter of 0.17–0.26 mm vs >0.7 mm for normal ducts.[214,215] Serious injury to the normal vas, bladder, ureter, or testis during hernia/hydrocele repair is uncommon (2%).[206,216,217] Even in the subset of boys requiring hernia repair in infancy for incarceration, the rate of testicular atrophy is low (2%).[218] Hernia recurrence is also rare (<0.5%). Postoperative (new or persistent) hydrocele may be found in 1.5–3.5% of cases but the majority resolve spontaneously within 1 year.

A more severe and unusual form of hydrocele is the abdominoscrotal hydrocele (ASH), which extends from scrotum to retroperitoneum but has no demonstrable communication with the peritoneal cavity.[219–221] Presentation is usually unilateral but may be bilateral. Bimanual examination confirms an abdominoscrotal mass which transmits a fluid wave; ultrasound may be useful to confirm the diagnosis in some cases. Often present at birth, the ASH may become quite large, extending laterally to the level of the umbilicus or higher. They often do not regress and may enlarge with time. They may rarely cause pain, lower extremity edema, hydronephrosis, and testicular atrophy.[221,222]

Proposed etiologies include isolated closure of the processus vaginalis at the internal ring with gradual upward extension of the hydrocele retroperitoneally, or incomplete proximal obliteration of the processus producing a one-way valve mechanism with continued accumulation of fluid.[219,220] Associated undescended testis may be present. ASH repair is generally performed through a standard inguinal incision, although inbrication of the wall transcrotally may be safer.[222] The sac is transected, the distal portion opened widely, and the retroperitoneal portion excised completely to prevent recurrence. Extreme care must be taken to avoid injury to local retroperitoneal structures, such as the vas or ureter, which may be difficult to identify in the folds of the large hydrocele wall.[219] For this reason the scrotal approach may be preferable. Concomitant orchidopexy is performed, if indicated.

Testicular abnormalities

Congenital testicular anomalies other than cryptorchidism are rare but are often found in association with abnormal testicular descent. Those associated with intersex disorders are reviewed elsewhere (see Chapter 68).

Defects of number and position

Anorchism and monorchism

Absence of one or both testes in otherwise normal phenotypic males is identified in as many as 35% of patients evaluated for non-palpable testes.[224–226] In the majority, the vas and spermatic vessels are present but end blindly distal to the internal inguinal ring, a condition called vanishing testis. Several observations indicate that the likely cause of vanishing testis is antenatal torsion. These include presence of hemosiderin or calcification in 15–85% of specimens examined histologically,[224–226] absence of developmental abnormalities in the contralateral testis,[227] and sonographic confirmation of prenatal testicular disappearance in a patient with extravaginal torsion.[228] The diagnosis of anorchism can be made after the first 3 months of age if both elevation of plasma gonadotropins and lack of testosterone response to hCG stimulation are present.[229] However, testosterone levels are elevated until about 2 months of age in the normal male. Therefore, absence of measurable levels in this age group suggests anorchia. During mid-childhood, gonadotropin levels may be normal in anorchid boys, but a GnRH stimulation test will reveal an exaggerated gonadotropin response. Contralateral testicular enlargement and elevated FSH levels are present in some, but not all, patients with monorchism.[230] Therefore, diagnosis must be based on laparoscopic and/or surgical findings of blind-ending spermatic vessels. Reduced levels of serum müllerian inhibiting substance may also prove useful in the diagnosis of anorchism.[232]

Polyorchidism

Supernumerary testis is a rare entity, with fewer than 100 case reports in the literature.[233–235] The proposed

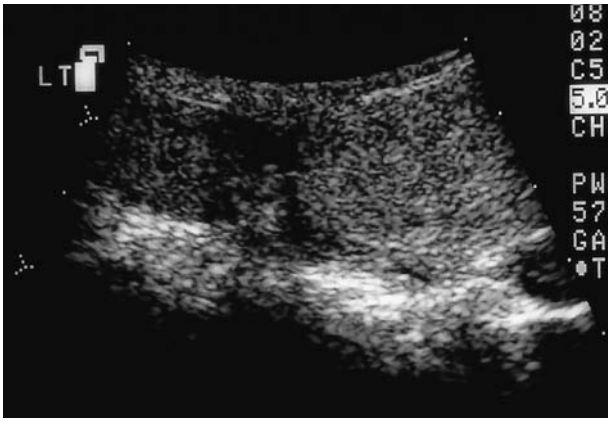

Figure 72.22 Polyorchidism: ultrasound image showing two normal testes on the left side.

etiology is complete duplication of the genital ridge or separation of the ridge into two or more parts. The extra testis is most commonly located in the scrotum (75%), but may be inguinal (20%) or retroperitoneal (5%). The condition is rarely bilateral (5%). Associated ductal structures on the affected side may be single or duplicated. The anatomic variants described in the literature include shared epididymis and vas (47%), duplicated epididymis and common vas (33%), duplicated epididymis and vas (11%), and absence of both adjacent to the accessory testis (5%). Associated genital anomalies are common and in decreasing order of frequency include inguinal hernia, undescended orthotopic testis, spermatic cord torsion, hydrocele, testicular tumor, and varicocele. The diagnosis is suspected by physical findings and can often be confirmed sonographically (Figure 72.22). Surgical intervention is indicated for torsion, hernia/hydrocele, suspected tumor, or cryptorchidism.

Testicular exstrophy

Congenital extrusion of one or both testes outside the scrotum is one of the rarest testicular anomalies.[236,237] There are inadequate data to support any specific etiology, but theories include gubernacular malfunction, scrotal ischemia, or local mesodermal abnormality. No associated anomalies are reported. Treatment is simple scrotal orchidopexy and closure.

Transverse testicular ectopia

The presence of both testes on the same side, each with an intact ipsilateral blood supply, epididymis, and vas, is an uncommon malformation.[238,239] The most frequent associated anomalies include inguinal hernia (98%) and persistent müllerian duct syndrome (30%). The absence of a normal attachment of the gubernacular remnant suggests that anomalous development of this structure may predispose to transverse ectopy. Laparoscopy may be useful for both diagnosis and management.[240–243] Depending on presentation, orchiectomy or orchidopexy is performed with partial excision of müllerian remnants as required to facilitate scrotal placement of the testis.

Other testicular anomalies

Gonadal fusion anomalies

Splenogonadal fusion is a rare anomaly characterized by an abnormal attachment between the left gonad or its internal ductal system and the spleen or accessory splenic tissue.[244–247] Almost 150 cases have been reported, with the majority occurring in males. Patients most commonly present with a scrotal mass, inguinal hernia, or undescended testis. Rare presentations include bowel obstruction, ambiguous genitalia, and acute enlargement or traumatic rupture of the scrotal spleen. Two variants are described: a continuous form characterized by a fibrous connection between gonad and spleen which may contain accessory 'spleenlets', and a discontinuous form, with no connection between the gonad and the orthotopic spleen. These subtypes occur with similar frequency. Other congenital anomalies are present in about one-third of cases, including limb, skull or cardiac defects, micrognathia, diaphragmatic hernia, imperforate anus, spina bifida, and hypospadias. Proposed etiologies include adhesion between splenic and gonadal tissue at 5–9 weeks' gestation due to simple fusion or inflammation[244] and migration of splenic cells into a persistent diaphragmatic gonadal ligament.[246] Treatment is based on associated findings, but care should be taken to avoid injury to the associated normal testis.[244]

A single case of hepatogonadal fusion has appeared in the relatively recent literature.[248] This patient presented with a right inguinal hernia, and had a histologically proven liver nodule attached to the upper testicular pole and a fibrous attachment to the porta hepatis. No other anomalies were present.

Testicular hypertrophy and macroorchidism

Testicular volume is usually less than 2 ml prior to puberty.[249,250] After the age of 9–10 years, testicular size is markedly variable but correlates with Tanner stage.[249] Unilateral or bilateral enlargement of the testis has many etiologies. Malignant lesions, including primary testicular tumors and leukemia, are rare

but should be ruled out initially. Benign causes of increased testicular size include asymmetric pubertal enlargement,[251,252] compensatory hypertrophy in some cases of monorchism or cryptorchidism,[253] macroorchidism associated with fragile X and other mental retardation syndromes,[254,255] nodular enlargement in patients with congenital adrenal hyperplasia[256] and isosexual precocity due to central nervous system (CNS) lesions, excess gonadotropins, testotoxicosis, hypothyroidism, and other syndromes.[257]

Testicular size discrepancy at puberty in otherwise normal boys is an uncommon finding. If a history of previous inguinal surgery or testicular injury is absent, the proposed cause is asymmetric response of the testis to normal maturational stimulation.[252] Exaggerated bilateral, benign testicular enlargement is also reported.[251] These patients should be evaluated with testicular sonography and, if a tumor is not identified, no further steps are indicated. Over time, the size discrepancy in unilateral cases may persist or resolve.[252]

Microlithiasis

Microlithiasis is a condition usually reported in adult men, but also found in children.[258] It is characterized by ultrasonic and/or histologic evidence of multiple calcifications within the testicular parenchyma (Figure 72.23).[259] Adult men with microlithiasis often present with other testicular disease, and associated germ cell tumors have been reported in as many as 40%.[260] By contrast, the prevalence of microlithiasis in men who have had testicular sonography for other reasons is 0.6%.[261] The exact incidence in the general population is unknown, but a study of 1504 young asymptomatic men 10–35 years old found a 5.6% prevalence of testicular microlithiasis.[262] A recent study by Wasniewska et al[263] revealed a high prevalence of testicular microlithiasis in males with McCune–Albright syndrome. Microlithiasis identified by pathologic examination is not always evident by sonography. However, the histologic type may be helpful in determining the significance of the lesion.[259] Hematoxylin bodies are associated with germ cell tumors, whereas laminated calcifications may be present in association with testis tumors, but also occur in normal boys and in other diseases affecting the testis including cryptorchidism, epididymitis, inguinal hernia, and Klinefelter's syndrome.

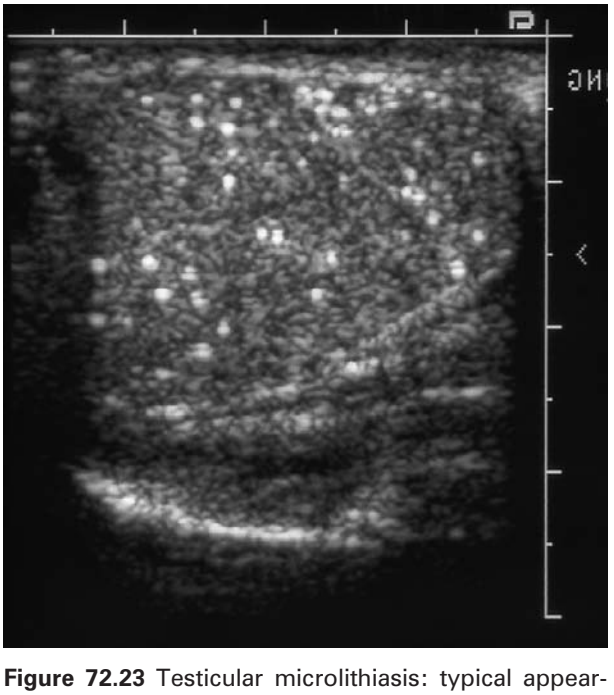

Figure 72.23 Testicular microlithiasis: typical appearance on ultrasound image.

Histologic microlithiasis is even rarer in the pediatric population, identified in only 1 of 2100 autopsies and 1 of 600 testicular biopsies.[264] In a multi-institutional series, Furness et al[258] studied 26 patients aged 6 months to 21 years (mean 12 years) in whom microlithiasis was diagnosed incidentally by sonogram. Reasons for evaluation included hydrocele, epididymitis, varicocele, trauma, testicular or appendix torsion, testicular mass, and unilateral testicular enlargement. There were no cases of clinically evident tumor during a mean follow-up period of slightly more than 2 years. Additionally, long-term data are required to identify the clinical significance, if any, of testicular microlithiasis in children. For the present, self-examination, yearly ultrasound imaging, and selected biopsy should be used in the surveillance of these patients.

Abnormalities of accessory organs

Cystic dysplasia of rete testis

Cystic dysplasia of the rete testes (also called cystic dysplasia of the testis) has been reported 32 times in the literature.[265–267] This lesion is believed to be due to a defect in fusion between the rete testis and efferent ducts. Cystic dysplasia is usually unilateral but may be bilateral, and patients often present in childhood with a testicular or scrotal mass. The diagnosis may be made by identifying multiple small cysts on the medical aspect of the testis, although most of the testicular parenchyma may be compressed by the mass. Associ-

ated genitourinary anomalies are common, suggesting that an associated wolffian duct anomaly may be present. Almost all cases are associated with renal anomalies. The most common are agenesis, dysplasia or hypoplasia, or hydronephrosis. Abdominal cryptorchidism is seen in one-third of patients. Preferred treatment is local excision, but an inguinal approach with control of the cord vessels is recommended to rule out tumor. Orchiectomy is performed if testis sparing is not possible. Cimador et al[268] suggests a more conservative approach with serial ultrasonography.

Wolffian duct system

Since the mesonephric or wolffian duct is the precursor of both ureteral bud and the internal genital ducts, including vas, epididymis, and seminal vesicles, anomalous development frequently affects both the kidney and reproductive tract.[269] The caudal segment of the wolffian duct, or common mesonephric duct, is the site of the origin of the ureteral bud. The middle segment, or common vas precursor, becomes the vas and seminal vesicles, and the upper mesonephric duct becomes the distal vas and epididymis.[270] It is proposed that defects that appear before the 7th week of gestation (onset of ureteral bud differentiation) may interfere with normal renal and reproductive tract development and after that time the reproductive tract alone is affected.[269] The timing and extent of the development defect probably influence the eventual phenotype.

Agenesis

Absence of the vas deferens is the most common finding in patients with agenesis of wolffian duct derivatives.[269,271–273] The lesion may be bilateral or unilateral and in either form occurs in less than 1% of males. Vasal agenesis is usually discovered in adult patients with infertility or at the time of planned vasectomy, but may also present during inguinal exploration at any age. Both the unilateral and bilateral forms are associated with agenesis of the epididymis, seminal vesicle and/or kidney, but the association is more frequent in unilateral cases. The caput epididymis almost always persists. This observation supports other clinical data indicating similarities between the caput epididymis and the efferent ducts, with the implication that the caput arises from the gonadal ridge rather than the wolffian duct. Mutation of the transmembrane conductance regulator (*CFTR*) gene is the only known genetic etiology of vasal agenesis. *CFTR* gene mutations are more common in bilateral (64%) than unilateral (25%) disease and have not been found in patients with bilateral vasal agenesis in association with renal anomalies.[269] When vasal agenesis is diagnosed in childhood, renal and pelvic sonography and, if abnormal, VCUG should be performed. Vasal agenesis may be found in patients with cystic fibrosis, even when clinical evidence of the disease is absent.

Anomalies of epididymal attachment

Abnormalities of fusion or suspension of the epididymis are known to be common in patients with cryptorchidism. Turek et al[274] studied epididymal anatomy in a group of boys undergoing inguinal or scrotal exploration primarily for hydrocele and reported normal anatomy in 96%. However, two other studies have shown a higher incidence (31–39%) of mild suspension or fusion anomalies of the epididymis in boys with hernia/hydrocele, with a greater frequency in those patients with a patent processus vaginalis.[275,276] The clinical significance of partial epididymal detachment or a long looping epididymis in patients with a normally positioned testis is unclear.

Epididymal cysts

Cysts of the epididymis (spermatocele) (Figure 72.24) usually appear during puberty or adulthood and are asymptomatic. The etiology is unknown but

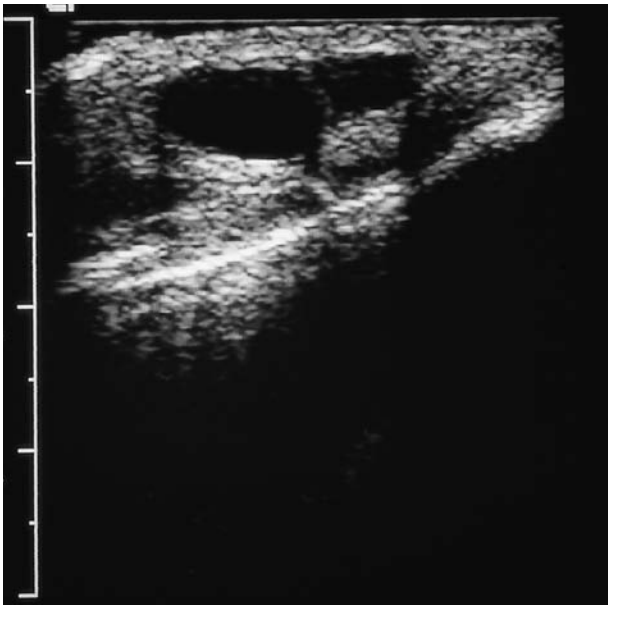

Figure 72.24 Epididymal cysts in a patient with polyorchidism.

proposed theories include dilated efferent ducts that have failed to fuse with the epididymis[269,277] and/or part of a testicular dysgenesis syndrome caused by an endocrine abnormality.[278,279] Conditions associated with a higher incidence of epididymal cysts include cryptorchidism, Von Hippel–Lindau disease and fetal exposure to diethylstilbestrol. Intervention is not usually required, but both excision[280] and sclerotherapy[281,282] have been used successfully in symptomatic patients. Two cases of torsion of an epididymal cyst have been reported.[283]

Other vasal anomalies

Ectopy of the vas deferens,[270,284,285] also called persisting mesonephric duct,[286] is characterized by ectopic insertion of the vas into the urinary tract. Most commonly, fusion of the vas and ureter occurs proximal to the bladder[287] (vasoureteric insertion), but direct entry of the vas into the bladder (vasovesical insertion) may occur. Approximately 30 cases are reported in the English literature. Proposed mechanisms include ectopic insertion of the ureteral bud and/or aberrant development of the proximal vas precursor.[270,286] Patients are asymptomatic or present with UTIs and/or epididymitis. Other congenital anomalies are common, including agenesis of the seminal vesicles, imperforate anus, hypospadias, ureteral reflux and/or ectopy, and renal anomalies. The triad of imperforate anus, hypospadias, and ectopic vas was reported in 21% of cases.[288] The diagnosis may be made by cystourethrography, retrograde ureterography, or at the time of ureteroneocystostomy. Treatment is based on anatomic findings and clinical indications.

True duplication of the vas deferens is extremely rare. Binderow et al[289] reported a single case found at the time of inguinal hernia repair in a boy with a normal urinary tract. The authors proposed wolffian duct duplication or ductal bifurcation in the region of the proximal vas precursor as the etiology.

Seminal vesicle cysts

Seminal vesicle cysts are another rare manifestation of anomalous wolffian duct development.[290–292] They may be congenital or acquired.[293] Most are associated with renal agenesis with or without ureteral ectopy. Presentation is predominantly in adulthood with pain during micturition, defecation or ejaculation, UTI, or infertility. A palpable mass is appreciated on rectal examination. The diagnosis may be confirmed by abdominal or transrectal sonogram. A computed topographic scan may be useful to visualize the semi-

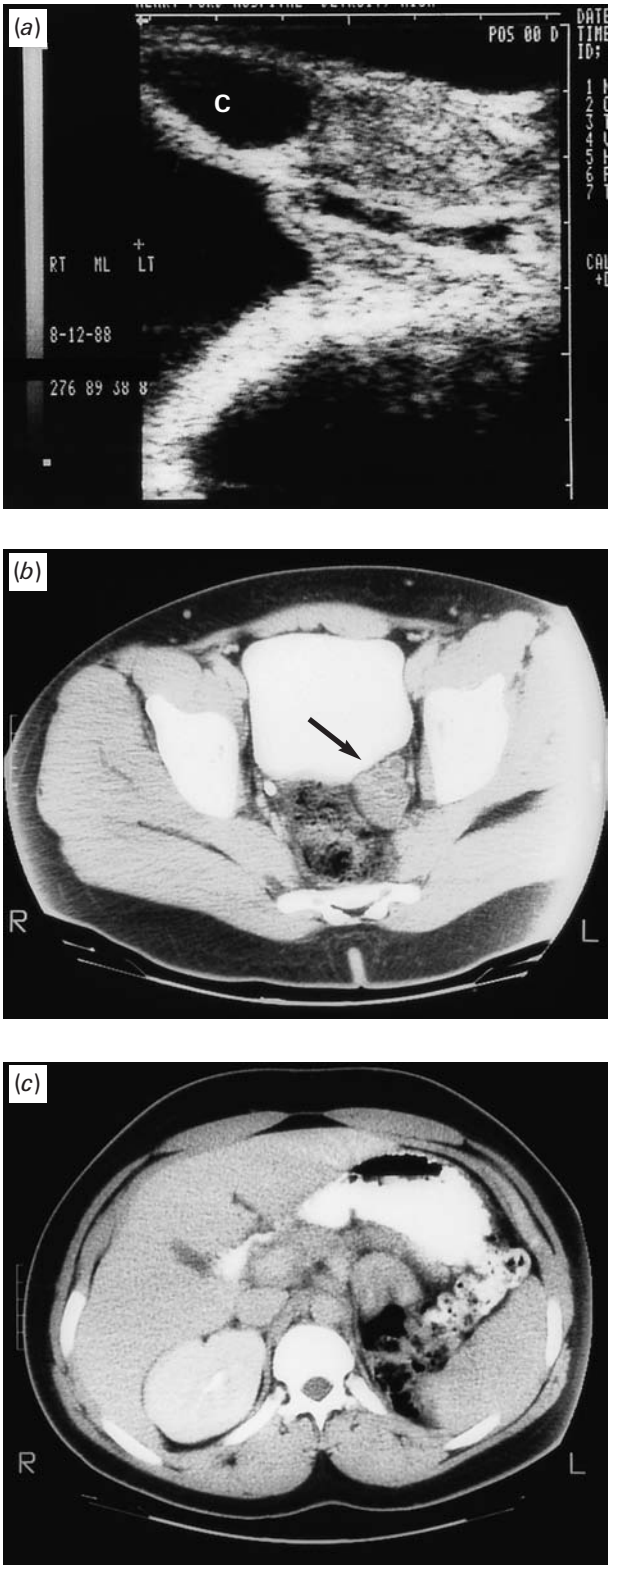

Figure 72.25 Seminal vesical cyst in an adolescent presenting with voiding symptoms and urinary tract infection: (*a*) sonogram showing a cystic structure posterior to the bladder in the left sagittal view (C); (*b*) computed tomographic (CT) scan confirming a fluid-filled structure (arrow) in the region of the left seminal vesicle; (*c*) absence of the left kidney on CT scan.

nal vesicle and confirm renal agenesis (Figure 72.25). Excision is indicated in symptomatic patients, either using an open technique, such as a transtrigonal approach,[292] or laparoscopically.[294–296]

Hernia, hydroceles, testicular torsion, and varicocele

73

Hiep T Nguyen

Problems associated with the testis such as hernia/hydrocele, testicular torsion, and varicocele are common in infants and children. Although these diagnoses can be difficult to make at times, problems associated with the testes mandate accurate and prompt recognition in order to prevent potential testicular damage or loss. Management options are often diverse and controversial, requiring the clinician to be aware of these issues in counseling the patients or their parents. These conditions can be corrected surgically, but there may be long-term consequences such as testicular atrophy and infertility that require further follow-up care after surgical management.

Hernia and hydrocele

Definition and incidence

A hernia is defined as a protrusion of organ or tissue through an abnormal opening in the abdominal wall muscle or fascia. A direct inguinal hernia results from a weakness in the floor of the inguinal canal, allowing abdominal content and fluid to herniate through the external ring, medial to the epigastric vessels. In contrast, an indirect inguinal hernia results from a patent processus vaginalis (PV), allowing abdominal content and fluid to herniate through the internal ring. A direct inguinal hernia is uncommon in children. A hydrocele is defined as an accumulation of fluid around the testis. A communicating hydrocele results from a patent PV in which the opening through the internal ring is small, allowing fluid but not bowel to enter the scrotum. A non-communicating hydrocele results from a patent PV in which the opening through the internal ring is closed but the rest of the PV is not completely obliterated. Since there is no communication with the peritoneum, the fluid in the non-communicating hydrocele originates from the mesothelial lining of tunica vaginalis as a result of inflammation of the testis or epididymitis. A communicating hydrocele is common in young children, whereas a non-communicating hydrocele is more common in adolescents.

Hernia and hydrocele occur in approximately 1–3% of full-term infants but are three times more common in premature infants.[1,2] With regards to hernia, the male to female ratio is 8 to 1. A hernia/hydrocele occurs more often on the right than left (2:1) and is present bilaterally in 16% of affected patients.[1] Ten percent of children with a hernia/hydrocele will have a positive family history. Approximately one-third of the children with a hernia/hydrocele will be diagnosed before 6 months of age. An increased incidence of hernia/hydrocele is seen in patients with cystic fibrosis (15%),[3] connective tissue disease such as Ehlers–Danlos syndrome and Hunter–Hurler syndrome,[4,5] and congenital hip dislocation.[6] Children with a ventriculoperitoneal (VP) shunt or on continuous ambulatory peritoneal dialysis (CAPD) are also at higher risk of developing a hernia/hydrocele.[7]

Etiology and pathophysiology

In the male fetus, the testes develop from the cranial end of the mesonephros. The gubernaculum forms from a band of condescended mesenchyme, connecting to the lower pole of each testis. Around the 8th week of gestation, an outpouching of mesothelial cells from the coelomic cavity grows into the substance of gubernacular mesenchyme, forming the processus vaginalis. The PV is composed of a lining of simple mesothelium, surrounded by a fibrous layer of vari-

able thickness and fatty connective tissue containing blood vessels, nerve trunks, lymph nodes, and variable amount of muscle.[8] The skeletal muscles of the PV are derived from the transverse abdominis muscle and the smooth muscle component is derived from the dartos muscles. Occasionally, the lining of PV undergoes proliferation due to chronic irritation. It may contain papillary structures or nodules. On histologic examination, fibrin deposition, extensive scarring, and psammoma bodies may be evident. In addition, mesothelial hyperplasia may be present with multinucleated cells, forming tubule-like structures within the fibrous tissue. These structures may appear to invade into the fibrous subserosa of the irritated PV. These features are often confused with those of rhabdomyosarcoma, mesothelioma, and metastatic carcinoma.[9]

By the 28th week of gestation, the testes begin to move from the posterior abdominal wall to the internal ring, as a result of growth of the fetal trunk and pelvis. The PV forms a channel through which the testes descend into the scrotum. It is believed that testicular descent is directed by the gubernacula[10] and assisted by the PV, which allows transmission of the abdominal pressure to the fetal testes, causing their descent through the inguinal canal.[11] The passage through the inguinal canal takes approximately 3 days and appears to be regulated by the genitofemoral nerve and the release of the calcitonin gene-related peptide (CGRP).[12,13] The testes enter the scrotum between the 32nd and 38th weeks of gestation; in some patients this process may be delayed up to the 40th week of gestation.

After the descent of the testes, the entrance to the inguinal canal, the internal ring, closes and the lumen of the PV is obliterated. Progressive fibrous obliteration of the PV occurs in a cephalad direction, beginning above the epididymis.[14] Organ culture of the PV from human infants demonstrates the presence of CGRP receptor on the mesechymal fibroblasts but not the epithelial cells. Addition of CGRP induces fusion of the PV through its effects on the fibroblasts.[13] In addition, it is observed that patency of the PV is often seen in association with epididymal abnormalities.[15] Since epididymal development is dependent on androgen stimulation, it is speculated that closure of the PV is also regulated by androgen. Another suggested mechanism to account for the persistently patent PV is the failure of the smooth muscle in PV to regress. Normally, these muscles disappear after taking part in the descent of the testis, a process that appears to be regulated by the autonomic system. In patients with a hernia, the muscles fail to undergo apoptosis and therefore maintain the patency of the PV.[16–19]

In the female fetus, the ovaries descend in a similar manner except that the process is halted in the pelvis. The cranial portion of the gubernaculum forms the ovarian ligament, and the caudal portion forms the round ligament, which runs from the uterus to the labia majora. It appears that the gubernaculum also plays a role in guiding ovarian descent.[20] Only rudimentary development of the PV occurs, forming the canal of Nuck.

Presentation and diagnosis

Children with a hernia/hydrocele often present with a history of a painless lump or bulge in the groin, scrotum, or labium (Figure 73.1). In younger children,

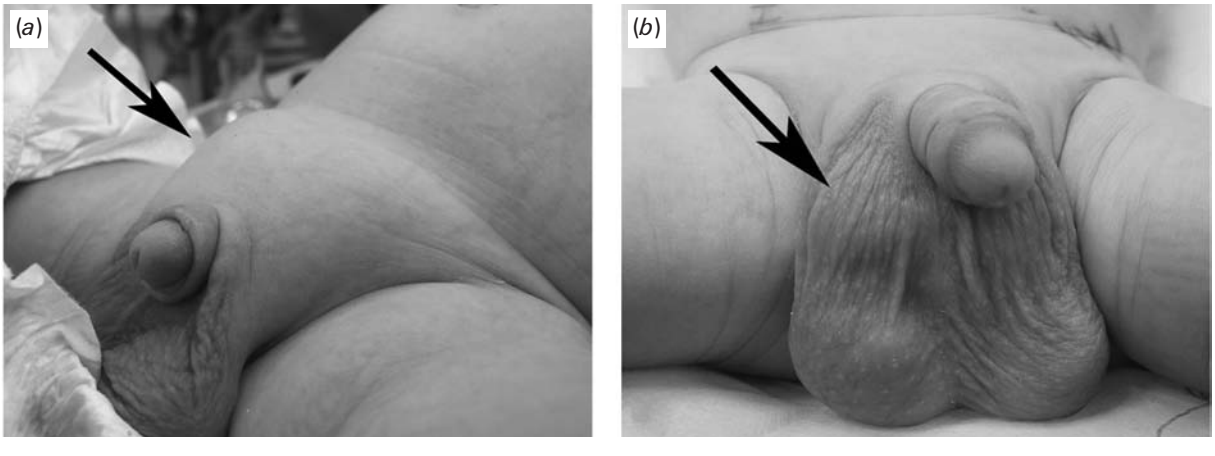

Figure 73.1 On physical examination, a bulge (arrows) can be seen in the groin (*a*) or in the scrotum (*b*), distinct from the testis in infants with an inguinal hernia.

this bulge may be more obvious while the child is crying, straining, or doing maneuvers that increase abdominal pressure. In older children, the hernia/hydrocele often gets larger during the day and smaller at night or during time of recumbency. Occasionally, a child may present with symptoms similar to that of acute testicular torsion, resulting from torsion of the hernia sac.[21,22] Approximately 10% of patients with an inguinal hernia present to medical attention with symptoms of bowel obstruction such as nausea, vomiting, abdominal distention, or localized or generalized abdominal tenderness.

On physical examination, bowel can be palpated or heard during manipulation of the inguinal or scrotal bulge in patients with a hernia. Occasionally, a silk glove sign can be detected on examination, as the layers of PV can be felt around the spermatic cord, feeling like silk rubbing on silk. It has been suggested that the silk glove sign is not from an empty hernia sac but from the hypertrophied cremasteric muscle fibers.[23] Unfortunately, this physical finding is very inaccurate in the absence of finding an obvious hernia/hydrocele.[24] It should be noted that in many patients with a hernia, there are no findings on physical examination, and the diagnosis is dependent upon the clinical history alone.

Typically, a non-tender bluish discoloration to scrotum and a soft mass around the testis is noted in patients with a hydrocele. In others, a painless mobile cystic swelling may be found anywhere along the spermatic cord. Termed a cord or encysted hydrocele, it is not reducible and can often be confused with a hernia.[25] Rarely, a child may present with an abdominoscrotal hydrocele in which a scrotal hydrocele has a dumbbell-shaped extension through the internal ring into the abdomen that forms an intra-abdominal cystic mass. In most patients, the hydrocele contains an exudative fluid. However, other fluid types have also been found in association with a hydrocele. A meconium hydrocele results from an in-utero perforation of bowel and subsequent inflammation and calcification of the meconium.[26] A pyocele can develop in association with acute appendicitis,[27,28] infection of the epididymis or testis, tuberculosis peritonitis,[29,30] or primary bacterial infection.[31] A pneumocele may develop as a consequence of necrotizing enterocolitis or other causes of bowel perforation.[32] A hematocele can form as a result of blunt abdominal trauma with associated splenic injury or scrotal injury.[33] A hydrocele may also contain ascites fluid such as bile, chyle, urine, cerebrospinal fluid in patients with a VP shunt, or dialysate fluid in patients on peritoneal dialysis. Hydrocele may also occur in girls, arising from the canal of Nuck.[34]

Being able to distinguish a hernia from a hydrocele on physical examination is often difficult. It has been suggested that transillumination may be used to identify a hydrocele (Figure 73.2). However, it

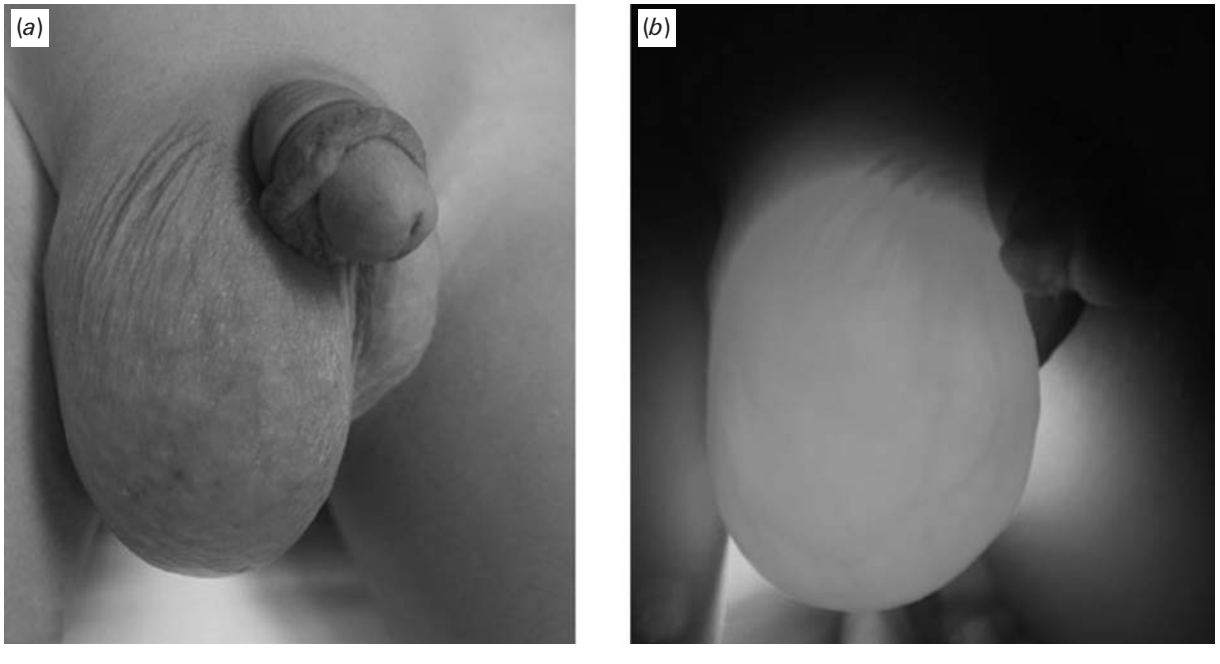

Figure 73.2 On physical examination of a boy with a hydrocele, scrotal swelling can be seen involving the testis (*a*) and this does transilluminate (*b*).

should be noted that since bowel fluid and air will transmit light in a similar manner as hydrocele fluid, this finding is not reliable. A scrotal mass that is easily reducible suggests a large patent PV representing either a hernia or a large communicating hydrocele. In contrast, a mass that is not reducible is likely to represent either a non-communicating hydrocele, one with a small patent internal ring, or an incarnated hernia.

In most patients with a hernia/hydrocele, the diagnosis can be made by clinical history and physical examination. In those few patients in whom the diagnosis cannot be well established, further radiologic examination may be helpful. In addition, when the testis cannot be palpated on physical examination, further radiologic imaging is required to rule out potentially serious pathologies such as undescended testis, infection, or testicular cancer. Ultrasonography (US) is widely used in evaluating inguinal and scrotal pathology. In patients with a hernia, fluid- or air-filled loops of bowel may be identified in the inguinal canal or scrotum. When there is omental herniation, a hyperechoic mass can be seen. However, it should be noted that US often fails to detect herniated bowel loops since the herniation is often periodic. In the absence of finding bowel or fluid in the inguinal canal, an increased cord width, as measured by US (7.2 ± 2.0 mm compared with 3.6 ± 0.8 mm in a normal inguinal canal), has been used to diagnose hernia.[35] In contrast, a hydrocele on US can be identified by identifying fluid in between tunical layers and the normal testis/epididymis. The hydrocele may contain loculations. Fine particulate matter seen on US may represent pus or blood, whereas calcification (seen as hyperechoic shadowing masses) suggests the presence of meconium.

Aside from US, other imaging techniques are seldom helpful in the diagnosis of a hernia/hydrocele. A KUB (kidney, ureter, and bladder X-ray) may demonstrate air or calcification in the scrotum, suggesting the presence of a pneumocele or meconium hydrocele, respectively. Herniography has been utilized in the diagnosis of a hernia.[36] Iothalamate solution (60%) is injected into the peritoneum. The patient is placed in an upright position for 10 minutes; a KUB or a computed tomography (CT) scan is obtained to identify contrast lining the patent PV/hernia sac.[37,38] Because of potentially serious complications such as bowel injury, contrast reaction, and peritoneal irritation, its use is limited to special circumstances such as in evaluating chronic groin pain.[39,40]

Management and techniques

Hernia repair

Currently, there is no effective medical management of a hernia; the use of a truss is primarily of historical interest. Since inguinal hernia is likely to persist indefinitely, it is recommend that children who are diagnosed with an inguinal hernia undergo surgical repair to prevent bowel incarceration and potential testicular atrophy. This is of particular importance in premature infants and neonates, who are higher risk of developing bowel incarceration while waiting for surgery.[41] In extremely premature infants, hernia repair can be safely deferred until the child is ready to be discharged from the neonatal unit.[42] It is reported that the success rate for hernia repair approaches 99%.

The type of surgical repair is dependent on the type of inguinal hernia. The direct inguinal hernia requires reconstruction of the floor of the inguinal canal with or without the use of prosthetic materials such as polypropylene, Dacron (polyethylene terephthalate), or PTFE (polytetrafluoroethylene). Since it is an uncommon type of hernia in children, a review of all types of direct inguinal hernia repair is beyond the scope of this chapter but is provided by Read.[43] Repair of the indirect hernia can be approached with either an open or a laparoscopic technique. Czerny and Banks first introduced the concept of high ligation of the hernia sac in 1877. In brief, an inguinal incision, which is preferably hidden in a skin crease, is made approximately one-third the distance from the pubic tubercle to the anterior iliac spine. Scarpa's fascia is next incised and the external oblique fascia is exposed. The shelving edge of the fascia is then defined with blunt dissection; this will allow for easier closure of the external oblique fascia later. To expose the inguinal canal, the fascia is incised along the direction of the fibers, parallel to the shelving edge over the external ring. After identifying the spermatic cord, the cremasteric muscles are separated to expose the hernia sac, which is located anterior and medial to the vas and testicular vessels. The hernia sac is carefully dissected from adjacent structures and divided between hemostats (Figure 73.3). The hernia sac is next freed proximally to the internal ring, where it is ligated with absorbable sutures. The distal portion of the hernia sac may be opened down to the testis to prevent hydrocele formation, although the necessity of this step is debated. A similar technique is done for the repair of inguinal hernia in girls (Figure 73.4). It is important in these patients to open the hernia sac to ensure that there are no herniated structures such as gonads or fal-

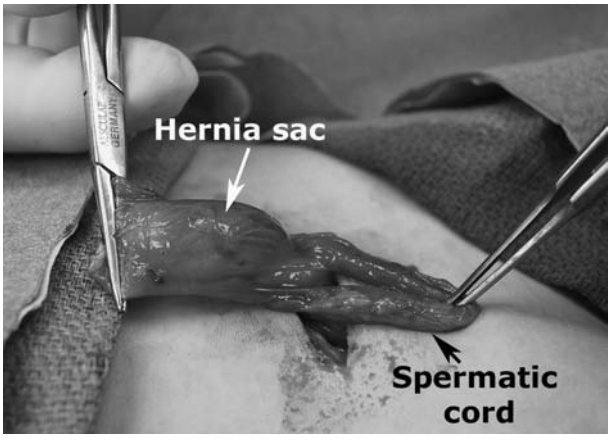

Figure 73.3 During the repair of an inguinal hernia, the hernia sac, which is located anterior medial to the spermatic cord, is carefully dissected away from the cord, ligated, and divided.

lopian tubes. Variations of this technique include approaching the hernia sac through a scrotal[44] or a low inguinal groove incision.[45] However, it should be noted that these approaches might limit the ability to ligate the hernia sac near the internal ring.

The repair of the indirect hernia may also be performed by laparoscopy. The internal ring can be approached either transperitoneally or preperitoneally[46] and the opening closed with a metal clip or sutures.[47] The surgical success rate using this technique is approximately 97%.[48,49] The laparoscopic approach is especially useful in patients with recurrent hernia. It allows for identification of the etiology of the recurrence such as incomplete ligation of the hernia sac, the de-novo development of a direct hernia, and the presence of other types of hernias such a femoral hernia.[50,51] More recently, the use of needlescopic hernia repair has been advocated. In brief, a 1.7 mm needle laparoscope is introduced through the umbilicus to visualize the opened internal ring. Through a second port positioned laterally, a grasper may be placed in the abdomen to help in the traction of the spermatic cord. A 2–3 mm incision is then made in skin directly over the internal ring and a suture is passed percutaneously anterolateral to the internal ring to perform an extraperitoneal high ligation of the hernia sac.[52] Long-term results and complication rates using this technique are not yet known.

Hydrocele repair

Unlike hernias, hydroceles may resolve spontaneously during the first year of life. Thus, in the absence of a hernia, surgical treatment for hydroceles can be deferred and observation is warranted. In older children who acutely present with a hydrocele, the underlying etiology such as epididymitis or orchitis should be treated. If the hydrocele persists several months after treatment, surgical repair may be considered. In young children, the hydrocele repair is performed in a similar manner to those described for repair of the indirect hernia, since these patients are likely to have a patent PV. In older children, the hydrocele repair can be performed through a midline or transverse scrotal incision since there is a low likelihood of a patent PV. The tunica vaginalis can be excised, everted (the bottle procedure), or imbricated (Lord's procedure). Sclerotherapy has been used in the treatment of hydroceles. The hydrocele is injected with a sclerosant such as tetracycline or polidocanol.[53] Complications include pain, long-term hazards of the sclerosant, and leakage

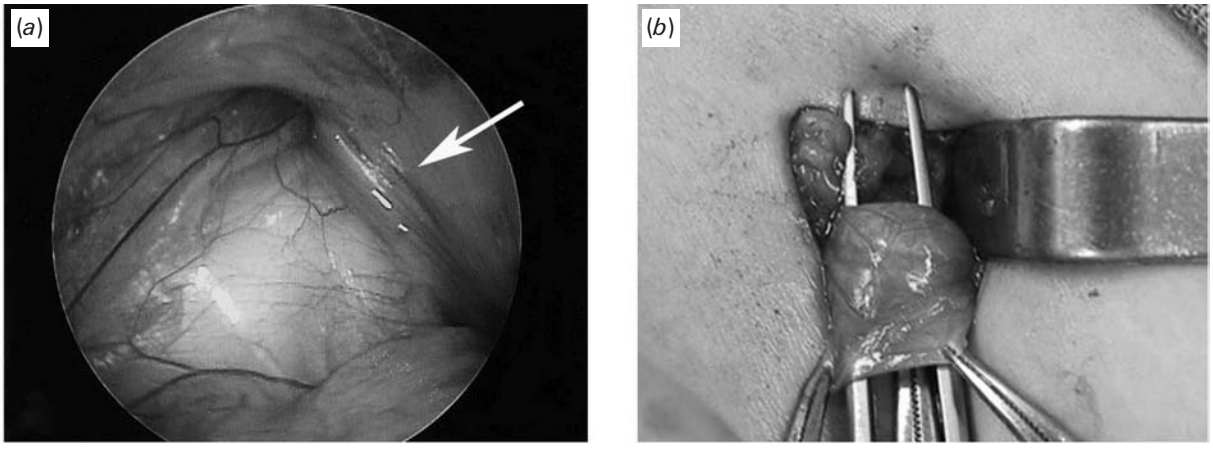

Figure 73.4 Inguinal hernia can also develop in girls. (*a*) On laparoscopy, an opened internal ring can be seen with the ovarian ligament (arrow) entering it. (*b*) On inguinal exploration, a hernia sac is identified. The hernia sac should be carefully examined to make sure that there are no structures herniating through the sac.

of the sclerosant through a patent PV. In addition, recurrence following treatment is common. Consequently, sclerotherapy is not recommended for children.

Potential structures encountered in the hernia sac during surgery

Numerous structures can be potentially encountered in the hernia sac; therefore, great care should be taken when dividing the sac. Typically, the hernia sac may contain intestine (small bowel, large bowel, appendix, and Meckel's diverticulum) or omentum. Occasionally, the bladder or intra-abdominal catheters such as a CAPD catheter or a VP shunt may herniate through the sac.[54] Less frequently, ectopic tissue such as that from the adrenal cortex,[55] spleen,[56] liver,[57] kidney,[58] and brain[59] can be found in the hernia sac. In a few rare cases (<0.1% of hernia repairs on adults and even less in children[60]), an unexpected discovery of a neoplasm is made during a hernia repair. Types of neoplasm found in the hernia sac include primary mesothelioma and liposarcomas,[55] extrarenal Wilms' tumor,[61] and metastatic cancer from the gastrointestinal tract, the ovaries, and the prostate.[8]

More frequently, the gonads and their associated structures may be encountered in the hernia sac. Despite having a palpable testis in the ipsilateral hemiscrotum, an additional testicle may be found at the time of hernia repair in boys with supernumerary testis[62] or cross-testicular ectopia. In approximately 2–3% of phenotypic girls undergoing hernia repair, a testis may be found in the sac, suggesting the diagnosis of complete androgen insensitivity syndrome (CAIS).[63,64] In these patients, the testis can either be removed after puberty to reduce the risk of germ cell malignancy (such as gonadoblastoma) or at the time of hernia repair to reduce the risk of virilization when the androgen insensitivity is not complete. An ovary can also be found in the hernia sac in 4% of girls undergoing surgery. Approximately 25% of these patients will have evidence of torsion effects or infarction in the herniated ovary.[65] Less often, genital duct structures are identified at the time of surgery or during pathologic evaluation. Functional wolffian duct derivatives such an accessory vas or epididymis may be seen separate from the spermatic cord, and should not be confused with true vasal injury. In patients with hernia uterine inguinale who have an anti-müllerian inhibiting factor or its receptor defect, persistent müllerian structures such as a uterus may be found in the hernia sac.[66,67] Owing to the close relationship with wolffian duct structures, great care has to be taken in excising the persistent müllerian structures. In 2–6% of the cases, non-functional müllerian or wolffian remnants structures can be identified in the hernia sac.[68,69] These structures are characterized by ciliated low columnar cells with occasional interspersed pale round cells, occurring singly, in small groups, or in large clusters.[70] They are smaller than functional duct derivatives and lack significant muscular coats. Given the potential for finding various structures in the sac, some clinicians have recommended sending the hernia sac routinely for pathologic examination. However, Miller et al[71] observed that in their series of 456 patients, only four cases (0.88%) had unexpected findings on pathologic evaluation of the hernia sac. None of these cases were of clinical significance (i.e. changed the patient management). The authors concluded that the routine histologic evaluation of inguinal hernia sacs in children is an unnecessary expense and should be reserved for select cases at the discretion of the surgeon.

Management of the contralateral patent processus vaginalis

In children who present with a unilateral hernia, much controversy exists as to the management of the contralateral side. Some surgeons recommend routinely exploring the opposite side for a patent PV, whereas others are more selective based upon clinical criteria such as age or sex.[72,73] Some utilize further radiologic imaging such as US[74] or perform diagnostic pneumoperitoneum[75] or laparoscopy through the umbilicus[76,77] or hernia sac[78,79] to diagnose a patent PV. Others just recommend observation for the development of a contralateral hernia. From autopsy studies, it is observed that the incidence of a patent PV is 90% in preterm infants, 80% in newborns, 60% in children less than 1 year of age, and 15–30% in adults.[80,81] From studies in which the patency of the contralateral PV was assessed in children with a unilateral hernia, it was observed that the incidence of a patent PV was also age dependent: approximately 60% of children <2 months of age who had a unilateral hernia had a patent contralateral PV; this incidence declined during the first 2 years of life and stabilized at 40% in children from 2 to 16 years of age.[73,82]

Several studies have also observed that the incidence of a contralateral hernia developing following unilateral hernia repair ranged from 3.6 to 10% (an average of approximately 7%),[83–87] far exceeding the

rate of a patent PV. Chertin et al similarly found that the incidence of developing a contralateral hernia in 300 girls who presented with a unilateral hernia and underwent a unilateral repair was 8%.[88] Using a univariate analysis with the Cox regression models, Ikeda et al observed that a left-sided hernia and a positive family history were significantly associated with the metachronous development of a contralateral hernia.[89] However, the incidence was at most 10%. Miltenburg et al performed a meta-analysis of the risk of metachronous hernia in infants and children and found that there was a 7% risk of developing a contralateral hernia following unilateral repair.[90] Gender and age were not risk factors. Similar to the findings by Ikeda et al,[89] there was an 11% risk of metachronous hernia if the original hernia was on the left side, a risk that was 50% greater than if the original hernia was on the right. Of patients who developed a metachronous hernia, 90% did so within 5 years, with a complication rate of 0.5%.[76] Based upon these findings, it can be concluded that patients with a patent PV do not necessarily progress to develop a clinically apparent inguinal hernia. Concurrent management of a contralateral PV is of probable benefit in premature and young infants where the risk of a second anesthesia is high and in children with risk factors for hernia recurrence such as cystic fibrosis or connective tissue disease. Interestingly, it was observed that in a study in which the parents were presented with the above issues and asked to choose between unilateral hernia repair only or with concomitant evaluation and repair of a contralateral patent PV for their child, 85% of the parents chose the latter.[91] Approximately 80% of those who chose contralateral exploration indicated that convenience was the primary motive in their choice and only 19% had concerns about their child undergoing a second anesthesia if a contralateral hernia develops later.

Complications of hernia/hydrocele repair

In general, the complication rate is higher in patients undergoing hernia repairs compared with those undergoing hydrocele repairs and in emergent compared with elective repair. The primary concern is associated with the anesthetic risk;[92] this is of particular significance in premature infants and in those <3 months of age. Improvements in pediatric anesthesia techniques such as the use of a laryngeal mask[93] with caudal[94] or local anesthesia and the use of regional anesthesia in premature infants[95] have greatly decreased the risk of potential anesthetic complications. Early complications associated with a hernia/hydrocele repair include local edema, hematoma, and wound infection. Early recurrence of inguinal/scrotal swelling result from a missed hernia or refilling of the potential space with fluid. Late complications include iatrogenic, upward displacement of the testis (incidence of 1% in children undergoing hernia repair),[96] paravesical abscess,[97] damage to spermatic cord, and recurrence. The incidence of spermatic cord injury during uncomplicated inguinal hernia surgery is approximately ≤1% during hydrocele repair.[98] However, if the hernia is incarcerated, the risk of spermatic cord injury increases significantly to 6–10%, with a subsequent testicular atrophy rate of 4%.[99] It is suggested that the bowel incarceration induces ischemia on the spermatic cord as a result of pressure. The rate of recurrence following open hernia/hydrocele repair is approximately 1–3%; however, it may be as high as 20% in premature infants undergoing repair.[43] Recurrence may be caused by failure to dissect a complete sac, tearing of the sac, or slipped sutures in ligating the sac. Moreover, in patients with recurrent hernia, other pathologies such as connective tissue diseases should be considered. Hydrocele formation following hernia repair either with an open or laparoscopic approach occurs in less than 1% of the patients.[48,49]

Testicular and appendiceal torsion

Definition and incidence

Normally, the tunica vaginalis covers the anterior surface of the testis, epididymis, and various distances over the spermatic cord. Attachment with the gubernaculum and scrotal wall posteriorly allows the testis to be fixed, preventing it from twisting around the vascular mesentery. However, when these attachments are not secure, torsion of the testis may occur, leading to vascular compromise. Although, testicular torsion can occur at any age, there is a bimodal distribution in the age of presentation, during puberty and during the neonatal period. More commonly in adolescents, testicular torsion involves torsion of the spermatic cord within the tunica vaginalis (intravaginal torsion). Owing to abnormal fixation of the testis and epididymis, the testis is freely suspended within the tunical cavity. This bell clapper deformity allows the testis to adopt a horizontal position in the scrotum (Figure 73.5a). It is found in 12% of testes at postmortem, and frequently occurs bilaterally.[100] It is the

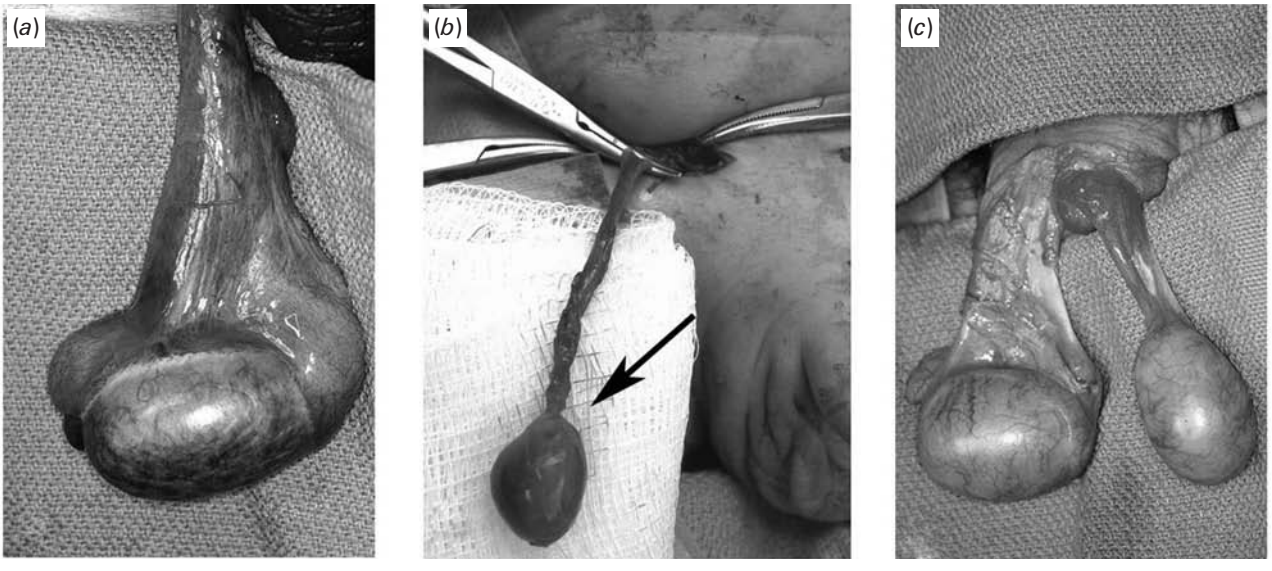

Figure 73.5 (*a*) In adolescents, testicular torsion occurs intravaginally, commonly due to the bell clapper deformity. (*b*) In neonates, testicular torsion occurs extravaginally, in which the entire cord is twisted about its axis (arrow). (*c*) In children with intermittent torsion, such as the one shown here who presented with intermittent left testicular pain, a bell clapper deformity (left testis) is often seen on the affected side.

most common etiology of torsion in adolescents, in whom rapidly increasing testicular mass associated with puberty increases the chance of the testis rotating. Intravaginal testicular torsion can also occur intermittently, spontaneously twisting and untwisting (Figure 73.5b).

Approximately 10% of all testicular torsion occurs in newborns. In 70% of these patients, torsion occurs prenatally and is diagnosed at the time of birth. In the other 30% of patients, torsion occurs in previously normal testes.[101] Testicular torsion in newborns occurs primarily extravaginally. In the neonatal period, the descending or recently descended testis and its coverings are very mobile within the scrotum, creating a risk for the spermatic cord to twist en masse (Figure 73.5c). Multiparity, excessive uterine pressure, and a strong cremasteric contraction have been suggested as etiologic factors for extravaginal torsion.[102]

Torsion of the testicular appendages may also occur. The appendix testis is a vestigial remnant of the müllerian system located on the upper pole of the testis. It is found in 90% of males and bilaterally in 60% (Figure 73.6a). Appendages may also be found on the epididymis (Figure 73.6b), epididymotesticular groove, or the cord itself. These appendages are remnants of the wolffian system. Approximately 95% of the appendiceal torsions involve the appendix testis. The peak age of presentation is around 10 years.[103] It has been suggested that hormonal stimulation during pubertal development increases the size of the testicular appendages, making them more susceptible to twisting around their small blood supply. In a review of 100 boys

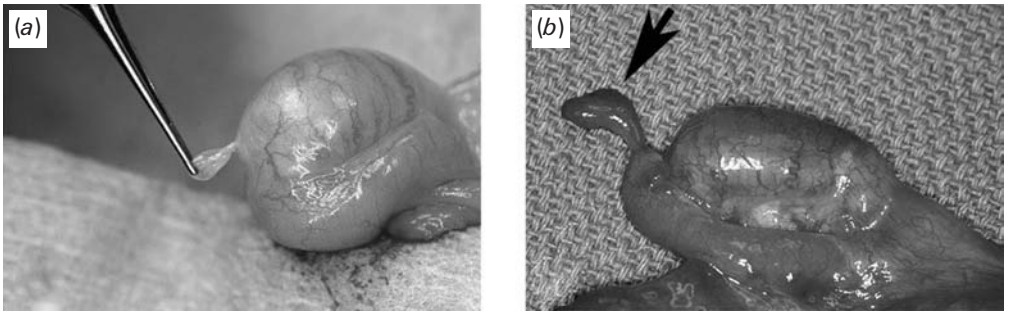

Figure 73.6 Acute testicular pain can also be due to torsion of the testicular appendages such as the appendix testis (*a*) and appendix epididymis (*b*) (arrow).

<15 years of age who presented with acute scrotal pain, Melekos et al[103] observed that 42% had testicular torsion and 32% had appendiceal torsion.

Presentation and diagnosis

Children and adolescents who present with an acute painful scrotum require prompt evaluation. Timely and accurate diagnosis is required to prevent testicular loss. Whereas the differential diagnosis is extensive (Table 73.1), the diagnosis can be determined based upon history, physical examination, and limited laboratory and radiologic evaluation. Typically, adolescents with intravaginal testicular torsion will present with acute onset of severe scrotal pain. In a series of 670 patients with acute testicular torsion, 89% of the patients presented with a complaint of acute-onset ipsilateral testicular pain.[104] The remaining patients presented only with pain referred to the ipsilateral lower abdomen, groin, or thigh. The majority of these patients were later found to have torsion in the undescended testis. Associated trauma and recent exercise was seen in 4% and 10% of the patients, respectively. About 11% of the patients were awakened from sleep with pain. Nausea and vomiting were associated with testicular torsion in 39% of the patients, whereas urinary symptoms such as dysuria and urgency were usually absent (<5%). Interestingly, 36% of the patients had a previous history of testicular pain or swelling. A prior history of ipsilateral orchidopexy does not exclude the diagnosis of testicular torsion. Inadequate fixation or the development of single adhesions forming an axis for the testis to twist has been observed in patients with a prior history of orchidopexy who presented with a recurrent testicular torsion.[105] Physical examination of the torsed testis is often very difficult due to the severity of the pain. Important signs of testicular torsion include a firm testicle high-riding in the scrotum, an abnormal transverse orientation of the testis, and the absence of a cremasteric reflex.[106] None of these physical findings is foolproof, and the clinician must maintain a high degree of suspicion. In many cases, acute hydrocele or marked scrotal edema develops when several hours have passed since the onset of the scrotal pain. Fever and an elevated white blood cell count are seldom associated with testicular torsion. Intermittent testicular torsion has a similar presentation to that of intravaginal torsion, except that the episode is self-limited with resolution of symptoms after the cord spontaneously untwists. Many patients who present with acute testicular torsion have a history of prior episodes consistent with intermittent testicular torsion. Those patients with intermittent torsion are likely to have normal physical examination at the time of evaluation, when the pain has resolved. In contrast to those patients with intravaginal torsion, patients with extravaginal neonatal torsion typically present with painless swelling and scrotal discoloration. A firm testis with an associated hydrocele is often noted incidentally on newborn examination or during diaper change. Interestingly, associated scrotal erythema is not often present, but the overlying skin is discolored by the underlying hemorrhagic necrosis.

Table 73.1 Differential diagnosis for acute/subacute scrotum

Testicular torsion
Appendiceal torsion (testis or epididymis)
Epididymitis/epididymo-orchitis
Inguinal hernia (reducible or incarcerated)
Hydrocele
Trauma (mechanical, burns, or animal/insect bite)
Testicular neoplasms
Spermatocele
Varicocele
Dermatologic lesions
Inflammatory vasculitis (Henoch–Schönlein purpura)
Idiopathic scrotal edema
Referred pain

Patients with appendiceal torsion can also present with pain similar to those with intravaginal testicular torsion. However, the presentation for appendiceal torsion can be quite variable, from an insidious onset of scrotal discomfort to acute severe scrotal pain. Consequently, it is often difficult to differentiate appendiceal torsion from other causes of acute scrotum. At the earlier stages, the pain may be localized to the upper pole of the testis or epididymis, and a firm nodule can sometimes be palpated in this region of the scrotum. The pain is more often of a gradual onset rather than developing acutely, and associated symptoms such as nausea, vomiting, and abdominal pain are unusual. On physical examination, the infarcted appendage can be seen through the scrotal skin as a blue dot; this is considered pathognomonic for appendiceal torsion. However, the blue dot sign is only seen in approximately 20% of patients with an appendiceal torsion.[103] In the latter stages, scrotal wall edema and erythema can develop, distorting the physical examination. The cremasteric reflex is usually preserved and the testis remains mobile.

In those patients who are suspected of having testicular torsion on a clinical basis, prompt surgical exploration is mandatory. Adjunctive radiologic tests should only be obtained when their purpose is to confirm the absence of testicular torsion so that surgical exploration can be avoided. These tests are also of use in patients in whom the duration of symptoms suggests a non-salvageable testis if torsion is the cause. In these limited cases, color or power Doppler US or ^{99m}Tc-radioisotope scintigraphy may be obtained to evaluate testicular blood flow. Both of these tests depend on the availability of equipment and personnel. False-negative results can occur with any of the above modalities. The choice of which study to obtain varies from institution to institution, depending on local experience and the availability and reliability of the tests. Color Doppler US studies can assess the anatomy of the scrotum and its content, while determining the presence or absence of testicular blood flow (as measured by velocity). The sensitivity of color Doppler US is reported to be as high as 90%, with a specificity of 99%.[107] However, caution must be used in the interpretation of these studies; almost 40% of patients, especially those younger than 8 years of age, may fail to demonstrate flow on the asymptomatic side.[108,109] Power Doppler US measures blood flow by detecting the number of red blood cells as opposed to the velocity of flow. Although blood flow is more consistently detected in younger children with power Doppler,[108] evidence from animal studies suggests that power Doppler and color Doppler are equally effective in the detection of torsion.[110] Radionuclide imaging was originally the study of choice for ruling out testicular torsion. However, it only allows for the assessment of blood flow. Its positive predictive value has been reported to be around 75%, with a sensitivity of 90% and a specificity of 89%.[111] Hyperemia of the scrotal wall can give false impressions of testicular blood flow. In addition, it is difficult to image children with small scrotal sacs or testes using this study.

Effects of unilateral torsion on testicular function

Ischemic damage from torsion is related to the duration of the torsion and the number of revolutions of the spermatic cord. Studies in dogs have demonstrated that no spermatogenic or Sertoli cells are viable after 6 hours of testicular ischemia, and all Leydig cells are lost after 10 hours of ischemia.[112] However, in humans, severe testicular atrophy can be seen as early as 4 hours when the degree of torsion is greater than 360°.[113] It is likely that when the cord is torsed >360°, the artery becomes completely occluded. In contrast, when the torsion is <360°, arteriolar stasis develops secondary to venous occlusion and edema. In general, testicular atrophy is rare before 8 hours of torsion but is common after this time period.[114] The mechanism of testicular damage appears to be related to a combination of ischemia and reperfusion injury, resulting from activation of the xanthine oxidase system in parenchymal cells or from leukocytes adherent to the reperfused venule walls.

The effects of ischemia do not seem to be limited to the torsed testis. In patients who had treatment of testicular torsion within 4 hours of the onset of symptoms, half of the patients had abnormal semen analysis in follow-up, suggesting injury to both testes.[114] Studies in rats have confirmed that unilateral torsion can induce bilateral testicular damage and reduced fertility.[115,116] Several mechanisms have been suggested to explain these observations, including an immunologic cause, congenital dysplasia, and damage of the normal testis by reflex vasoconstriction. It is suggested that torsion disrupts the normal blood–testis barrier, allowing the release of sperm antigens from the damaged testis. The antigens induce formation of autoantibodies, which can then attack the unaffected testis. In rats, it has been demonstrated that orchidectomy of the torsed testis, treatment with perioperative antilymphocyte globulin, and splenectomy,[117] or administration of immunosuppressants such as steroids and cyclosporine,[118] can prevent contralateral testicular damage. Similarly, in humans, patients with torsion for >24 hours who had undergone an orchidectomy are more likely to have a normal semen analysis than those in whom the torsed testis was left in place.[114] Although there is ample evidence in animal studies that damage of the contralateral testis is mediated by an immune response, direct evidence in human studies is lacking. Antitestis antibodies have been found in only approximately 10–20% of patients who had a testicular torsion.[119,120] In addition, their presence does not correlate with infertility or with any testicular exocrine or endocrine dysfunction. An alternative explanation for the observed abnormal semen parameters in patients with unilateral torsion is the presence of underlying congenital dysplasia in the unaffected testis. Biopsies from the contralateral testis at the time of treatment for unilateral torsion demonstrate abnormalities such as desquamation of the ger-

minative epithelium, atrophy of the Leydig cells, and malformation of spermatoblasts in 88% of the cases.[121] The presence of these abnormalities so soon after the onset of torsion suggests that there may be pre-existing underlying pathology in contralateral testis. However, this explanation does not explain the consistent correlation between the duration of torsion and total sperm count, unless the damage is compounded by another mechanism.[122] The most recent explanation of the observed damage in the non-torsed testis is that it is caused by ischemia induced by reflex vasoconstriction. In animal studies,[123–125] unilateral testicular torsion induces an immediate and progressive decrease in blood flow to the contralateral testis followed by a gradual increase after detorsion. Like the affected side, the contralateral testis can be damaged by a combination of ischemia and reperfusion injury. The effect of torsion on contralateral testicular blood flow appears to be mediated by sympathetic nerve discharges from the genitofemoral nerve.[126]

Several studies have suggested that testicular damage after torsion can be limited by cooling of the testes, suppressing immune-mediated damage, and chemical sympathectomy to prevent reflex vasoconstriction. In animal studies, external cooling of the testis can delay the effects of ischemia for a few hours.[127] In addition, verapamil, surfactant, allopurinol, platelet-activating factor inhibitors, and hyperbaric oxygen have been used in attempt to decrease reperfusion injury.[118,128,129] Similarly, immunosuppression with steroids, cyclosporine, and azathioprine has also been used to reduce testicular damage induced by an immune response.[130] Drugs such as capsaicin, 6-hydroxydopamine hydrobromide, guanethidine monosulfate, and nitric oxide have been shown in animal studies to reduce testicular damage by preventing vasospasm and hypoxia in the contralateral testis.[131,132] Apart from hypothermia, the other methods of limiting testicular damage following unilateral torsion have been used in humans.[133]

Treatment

When suspected of having testicular torsion, the patient should be taken to surgery without delay. Manual detorsion may be tried if surgical intervention cannot be done for a period of time. The testis should be turned caudal to cranial, and medial to lateral.[134] If the first attempt is unsuccessful, the testis should be turned in the opposite direction. If the detorsion is successful, the pain should resolve immediately. However, this process is often very painful, and manual detorsion may not completely correct the obstructed blood flow. Consequently, surgical intervention is still required following manual detorsion.

Fixation can be accomplished by securing the testis to the septum or placement into a dartos pouch. For trans-septal fixation, the scrotum is opened through an incision in the median raphe. For the pouch fixation, the incision is made transversely following the skin creases of the scrotum. When using the latter method, the dartos pouch is made after the skin is incised. The tunica vaginalis is then entered, and the testis is examined. The spermatic cord should be detorsed to restore blood flow. The affected testis should be placed in a warm sponge and observed for several minutes to determine viability. If it is nonviable, the necrotic testis should be removed. Exploration of the contralateral testis should also be performed and, in all cases, the contralateral testis must be fixed. The testicles can be fixed to the median septum with three or four fine, non-reactive and non-absorbable sutures. These sutures can be brought through the septum, enabling the contralateral side to be fixed concurrently. Alternatively, a dartos pouch is created and fixation relies on scarification of the testis. The tunica vaginalis is everted and the testicle placed into the dartos pouch. A non-absorbable suture is then used to secure the dartos tissue around the cord. This technique is advantageous in that complications such as abscess formation and tubular atrophy are uncommon. In addition, there have been no reported cases of recurrent torsion with this technique. Intermittent torsion is corrected using either of the above techniques on a semiemergent basis. As a result of the effects of torsion on the function of the affected and unaffected testis, these patients will require further follow-up care to evaluate for infertility.

The treatment of neonatal torsion is controversial. Some clinicians suggest that surgical exploration is unnecessary, whereas others advocate immediate surgical exploration and fixation of the contralateral side. It is rare to salvage the affected testis in a patient with unilateral neonatal torsion; out of more than 30 cases of bilateral neonatal torsion reported in the literature, only two testicles have been successfully salvaged.[135] Important reasons for exploration are to exclude tumor and to prevent possible unilateral torsion from becoming bilateral anorchia.[101] In the rare case of bilateral neonatal torsion, a more conservative approach can be taken. The newborn's general condition and anesthetic considerations should be evaluated to determine whether or not to proceed with surgical intervention.

The treatment of twisted testicular appendages is non-surgical if the diagnosis is certain. Conservative therapy with limitation of activity, scrotal elevation, and administration of non-steroidal analgesics is highly effective. Most of the symptoms will dissipate once the acute changes of acute necrosis resolve. In rare instances, surgical exploration may be undertaken if conservative management fails. Simple excision of the torsed appendage is curative. Although an asymptomatic appendage is likely to be present on the contralateral side, exploration of the unaffected testis is not indicated. Some clinicians have advocated surgical treatment for the management of appendiceal torsion because these patients seem to recover more rapidly and return to normal activity quicker than those treated conservatively.[136]

Varicocele

Definition and incidence

A varicocele is caused by abnormal dilation of the internal spermatic vein and the pampiniform plexus of the testis. There are three primary vascular suppliers to the testis: the internal spermatic, the vassal, and cremasteric artery and vein. At testicular levels, there is free communication between the arteries. The pampiniform plexus is formed from veins providing the drainage from the testis and epididymis. As this plexus courses toward its drainage into the renal vein on the left and the inferior vena cava on the right, it becomes the internal spermatic vein. Like the arteries, there is free communication between the pampiniform plexus and the vasal vein, which drains via the inferior vesical vein into the hypogastric vein, and the cremasteric vein, which drains via the inferior epigastric vein into the external iliac vein. In addition, the distal portion of the pampiniform plexus is also drained via the anterior scrotal vein into the femoral vein.

A varicocele is rarely seen in boys less than 10 years of age.[137] Its incidence rapidly increases between 10 and 15 years of age, and it is seen in approximately 15% of male adults.[138] There appears to be a causal relationship between pubertal development and varicocele formation. Varicocele may be classified by size during examination with the patient standing: grade I varicocele is not visible but becomes palpable during the Valsava maneuver; grade II varicocele is easily palpable on examination without the need for the Valsava maneuver; and grade III varicocele is clearly visible on examination. Grade I varicocele is seen in approximately 9% of adolescent males, whereas grade II is seen in 4% and grade III in 2%.[139] The true incidence of varicocele may be underestimated, since many adolescent males do not routinely undergo proper testicular examination in the upright position. Approximately 90% of varicoceles detected are found on the left side, whereas bilateral varicoceles occur in 2–10% of the cases. An isolated, right-sided varicocele is uncommon, and its presence should raise the suspicion of a pelvic mass compressing venous return.

Etiology and pathophysiology

There are many theories as to the etiology of a varicocele. It is speculated that there are incompetent or absent valves in the left spermatic vein, which allows retrograde blood flow into the pampiniform plexus.[140] It has also been hypothesized that the anatomic differences between the left and right spermatic veins (with the left being longer and having a right angle insertion into the left renal vein) allow for preferential transmission of higher hydrostatic pressures to the left pampiniform plexus. Alternatively, it has been suggested that a varicocele develops as a consequence of the left renal vein being compressed as it passes between the aorta and the superior mesenteric artery. However, this 'nutcracker effect' has not been seen clinically.[141] Finally, it is hypothesized that a varicocele develops from abnormal embryonic transformation of the primary venous system into the secondary system. The inferior vena cava is formed as the subcardinal, the posterior cardinal, and the supracardinal veins involute. Disordered involution may cause a persistence of intercardinal anastomoses that could lead to the formation of the varicocele.[141]

Although the etiology of a varicocele remains unclear, its effect on the testis is well documented. Biopsies from the testes of men with unilateral varicocele and fertility problems demonstrate incomplete maturational arrest at the spermatid and spermatocyte levels.[142,143] In addition, there is decreased spermatogenesis and seminiferous tubular thickening with decreased tubular diameter. Interestingly, these changes are seen in both testes but are more severe on the varicocele side.[142] It has also been observed that there are changes in the other components of the testis. Leydig cell hyperplasia is seen in association with varicocele. Its presence can be used for prognosis, since the pregnancy rate was observed to be decreased from 40% to 5% in partners of men with a varicocele who have Leydig cell hyperplasia on testic-

ular biopsy.[144] Sertoli cell abnormalities have also been reported in men with varicocele. On light and electron microscopy, spermatids are seen to be maloriented relative to Sertoli cells, and Sertoli–germ cell junctional complexes appear to be structurally abnormal.[145] Finally, the testicular microvasculature is also affected in adolescents and men with varicocele, in which proliferative endothelial lesions in the capillaries are seen. These vascular lesions precede the testicular changes and are reversible with surgical correction.[146] All of these findings must be interpreted with caution, as they come from men with fertility problems. Most men with varicocele are fertile.

Varicocele is also associated with specific biochemical changes. It has been observed that there is decreased intratesticular testosterone concentration in some adult men with varicocele.[147] It is not surprising that this decrease correlates with impaired spermatogenesis and Leydig cell changes in men with varicocele.[147,148] Similarly, a decrease in serum testosterone has been noted in some men with bilateral grade III varicoceles.[149] However, this observation is not seen in patients with other grades of varicocele.[150] Inhibin B is a glycoprotein produced by Sertoli cells that can potentially serve as a maker of Sertoli cell function in patients with varicocele. It is observed that serum inhibin B levels tend to be positively correlated with sperm concentration in some patients.[150,151] In comparison, it is more consistently observed that men[152,153] and adolescents[154] with varicocele have elevated gonadotropic hormones such as follicle-stimulating hormone (FSH). In addition, excessive gonadotropin (in particular FSH) response to gonadotropin-releasing hormone (GnRH) is seen in some adolescents with varicocele. In one study,[155] it was observed that 31% of adolescents with a unilateral varicocele had an abnormal response to GnRH stimulation, and 75% of those with testicular hypotrophy of >3 ml differential had an abnormal response. However, it should be noted that 54% of those who did not have elevated FSH and luteinizing hormone (LH) in response to GnRH stimulation also had hypotrophy. Aragona et al[156] observed a correlation between abnormal testis histology and an exaggerated response to GnRH. This abnormal GnRH response appears to be limited to those patients at Tanner stage V. Approximately 40% of the Tanner stage V patients had an exaggerated response to GnRH, whereas those patients with Tanner stages III and IV had no difference in LH or FSH response to GnRH.[157] Unfortunately, the use of GnRH as a predictor for the need for surgery is limited, since it does not correlate with the grade of the varicocele, testicular hypotrophy, or fertility.[157,158]

Since 98% of the testicular mass is composed of seminiferous tubules and germinal cells, it is not surprising that the histologic, deleterious effects of varicocele may be seen grossly by changes in testicular volume. The average size of the testis in an adult male is 24 ± 3 ml. Normally, there is no more than 2 ml difference. It has long been noted that the ipsilateral testis of patients with a unilateral varicocele can be significantly smaller than the contralateral side.[159] It should be noted, however, that in adult men, although a varicocele can cause significant ipsilateral testicular atrophy/hypotrophy, there does not seem to be a correlation between loss of testicular volume and fertility status in men with a left varicocele.[160] In adolescents, absolute changes in testicular volume cannot be used, since the testis is growing during puberty. Consequently, the percent volume loss compared with the right side is utilized. Like adult men, adolescents with a unilateral varicocele may have a significant amount of testicular volume loss. It remains a topic of debate as to what percentage of volume loss is considered significant (10% vs 25%).[161,162] Nevertheless, it has been observed that volume loss is seen in 34% of adolescents with grade II varicocele and 81% with grade III varicocele.[138] Several prospective studies[156,161,163] have demonstrated that in adolescents the testicular volume either fails to increase or even decreases in the presence of the varicocele.

The effects of the varicocele can also be seen in the semen quality. A 'stress pattern' can be observed in the semen of adults with a varicocele in approximately 90% of cases.[164] These characteristic changes consist of subnormal motility, an increase in immature forms, a shift from oval to tapered, and amorphous sperm forms.[165] These changes may worsen over time.[166] In adolescents, varicocele is associated with impairment in sperm motility and morphology, with no significant difference in sperm counts.[167] Surgical correction of the varicocele in adulthood[168–170] or in adolescence[161,171–173] results in improved semen parameters. In the only prospective study,[174] only improvement in sperm concentration was noted in adolescents with a unilateral varicocele who underwent surgical correction.

Several theories have been suggested for the etiology of how a varicocele induces these changes to the testis. It is speculated that these changes may be mediated by increased venous pressure or retrograde flow of toxic metabolites from the adrenal gland. Currently, the most plausible theory is that a varicocele induces thermal damage to the testis. Intratesticular

temperature is normally maintained at approximately 33–34°C. A countercurrent heat exchange between the blood coming down and the blood leaving the testis allows the testis to be maintained at a lower temperature. It is suggested that a varicocele disrupts this countercurrent heat exchange and induces testicular hyperthermia, which interferes with normal spermatogenesis.[175] This theory has been demonstrated in animal models of varicocele (reviewed by Turner[176]). In primates,[177] dogs,[178] and rats,[179] partial ligation of the left renal vein results in varicosity of the left spermatic vein and the pampiniform plexus. The surgically created varicocele induces bilateral increases in testicular blood flow and temperature, resulting in decreases in intratesticular testosterone and sperm output.[176] These effects do not appear to be immunologically or neurologically mediated[180] and are reversed with varicocelectomy.[181,182]

Presentation and diagnosis

The majority of adolescents who present with a unilateral varicocele are asymptomatic; pain or a dull nagging ache is the presenting symptom only in approximately 3% of the patients.[183] The varicocele is usually detected on a physical examination as a scrotal swelling/mass. To evaluate for the presence of a varicocele, it is essential to examine the patient standing up and then performing the Valsava maneuver. In addition, the testes should be carefully evaluated for their size and consistency. Several methods of testicular measurements, including rulers and calipers, orchidometers, and US, have been employed. Measurement using orchidometers such as the Prader or Rochester (Takihara) is readily available and inexpensive; however, the accuracy of the measurement is highly dependent upon the experience of the examiner. In comparison, measurement using testicular US is better correlated with actual testicular volume[184,185] but is more costly. Another advantage of using US in evaluating varicocele is its ability to pick up unexpected pathology such as a retroperitoneal mass, intratesticular varicocele, or testicular mass. An intratesticular varicocele is seen on scrotal Doppler US as an intratesticular anechoic lesion with active Doppler flow. It is found in association with traditionally large extratesticular varicoceles and has been shown to resolve following spermatic vein ligation.[186]

When possible, a semen analysis should be obtained. Semen quality is a good indicator of testicular function in adults with varicocele. However, it should be noted that its use in adolescents with a varicocele has some potential limitations: often it is very difficult to obtain semen analysis in adolescents due to ethical concerns. In addition, normal semen parameters have not been well defined prior to sexual maturity; between 12 and 19 years of age, spermatozoa are absent and semen parameters reach adult values 29–33 months after the onset of puberty.[187] Consequently, the interpretation of semen parameters is problematic in adolescents who are undergoing pubertal changes, and most practitioners do not routinely obtain semen specimens.

Serum measurement of FSH with or without GnRH stimulation may be potentially helpful in identifying those patients with testicular dysfunction induced by a varicocele. However, as indicated previously, elevation in FSH levels and abnormal GnRH responses do not always correlate with abnormal semen parameters or fertility. In addition, not all patients with testicular dysfunction have elevated FSH or abnormal response to GnRH. Consequently, their routine use in evaluating adolescents with varicocele is limited.

In a very selected group of patients, further radiologic imaging may be utilized in the evaluation of a varicocele. Internal spermatic vein venography can delineate the anatomy of the varicocele; however, it is costly and invasive. Its use tends to be limited to selected patients with recurrent varicocele[188] or during intraoperative evaluation.[189] Another method in the evaluation of a varicocele is the use of scrotal thermography to measure the scrotal temperature.[190,191] It is suggested that the observed increase in testicular temperature might identify those patients at risk for varicocele-induced testicular damage. Owing to a lack of correlation with outcome, this method is not in common use in the USA today. Color Doppler US may also be used to evaluate for the presence of a varicocele (Figure 73.7). It is able to define the number of dilated veins as well as the severity of dilation. However, with these various radiologic methods, many subclinical varicoceles can be identified (i.e. those that are not palpable on physical examination but are visualized with radiologic imaging.). Using contact thermography and venography, approximately 7% of those with a left-sided and 86% of those with right-sided varicocele are identified in the absence of findings on physical examination in adolescents who present for evaluation of a varicocele.[192] Because subclinical varicoceles are seen in approximately 60% of men attending fertility clinics but also in 40% of fertile men,[193,194] the clinical rele-

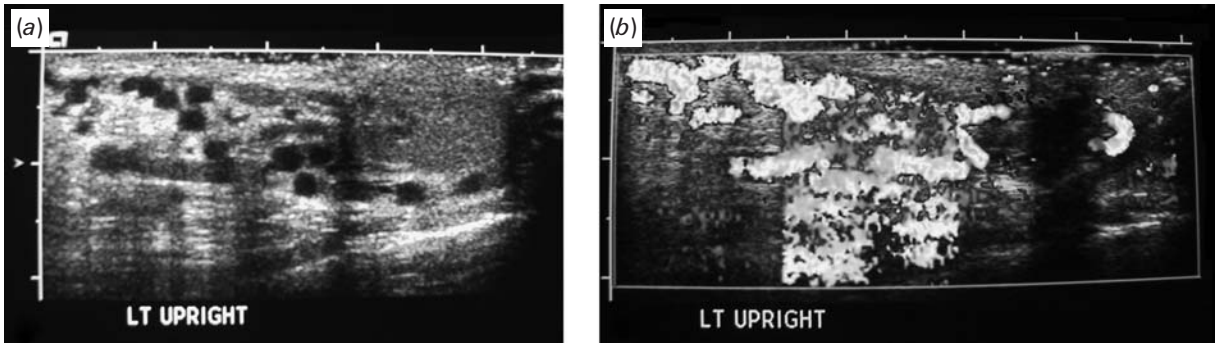

Figure 73.7 On ultrasonography (US), a varicocele can be identified by its 'Swiss-cheese' appearance (*a*). Doppler US can demonstrate retrograde flow in the varicocele (*b*).

vance and therefore the importance of diagnosing subclinical varicoceles are highly debated.

Treatment

Since 15% of adult men have a varicocele but only 20% of them have infertility, observation is a valid option in the management of patients with a varicocele. The risk in observing these patients is that some of them may demonstrate deterioration in the semen parameters and may progress to infertility. Although surgical correction reverses these changes in at least 50% of adult men, in others it does not, suggesting a potential for developing irreversible damage. Consequently, early surgical correction of adolescent varicocele has been advocated. This recommendation is based upon the assumption that adolescent varicocele is a progressive disease. In the only prospective longitudinal study in adults,[195] semen quality in men with untreated varicocele did not decline with time. However, most of the men had a semen quality at baseline that was worse than that of the controls. In the two studies of adolescent varicocele,[173,174] the authors observed lower semen quality in those who underwent varicocele repair compared with those who were not treated. However, it should be noted that in the first study there was no sequential semen analysis and in the second, the untreated group had similar semen parameters compared with controls. In another study,[196] a group of adolescents with a unilateral varicocele was followed with serial examinations, with a mean follow-up between the first and second examinations of 16 months. There was neither an increase in varicocele grade nor a change in testicular volume differentials over time, suggesting that perhaps adolescent varicocele is not a progressive disease. However, the limitations of this study are length of follow-up time and correlation with other parameters such as semen analysis. Currently, there are no convincing data supporting or refuting the premise that adolescent varicocele is a progressive disease.

Consequently, with the goal of preserving fertility, it is important to identify those adolescents with varicocele who would benefit from early intervention. It is generally agreed upon that an indication for surgical intervention is for symptoms such as pain. Although an uncommon complaint, 80–90% of those patients who undergo varicocele repair will have resolution of their symptoms.[183] In addition, those adolescents with bilateral varicoceles may benefit from surgery, since it is difficult to follow their testicular growth as both sides are affected. Similarly, in older patients with abnormal semen parameters on serial evaluation, surgical intervention would be indicated, allowing for potential improvement in semen parameters[172,173] and fertility.[197]

Other indications for varicocele repair in adolescents are more controversial. When semen analysis is not available, marked testicular volume differential is used as an indication for surgery. In adult men with a unilateral varicocele, testicular hypotrophy is associated with decreased total motile sperm counts.[198] However, there does not appear to be a correlation between the loss of testis volume and fertility status.[160] Nevertheless, surgical intervention does reverse the growth loss in adolescents with a unilateral varicocele.[167,172–174] Although it remains unclear whether varicocele repair solely for the purpose of reversing testicular hypotrophy improves future fertility potential, most would agree on this as an indication for intervention, in the absence of semen analysis. Size (i.e. grade) of the varicocele has also been suggested as a potential indicator for surgical intervention. It was observed that in infertile patients with grade III varicocele, there was a greater improvement in sperm concentration and motility than in those

patients with grade I or II varicocele.[199] However, there was no difference in fertility rates in those with large or small varicocele who underwent repair.[199,200] Consequently, the grade of the varicocele in itself is not predictive of the need for surgical intervention. Similarly, the finding of a 'soft' testis in association with the varicocele is not a strong indication for surgery. This finding is quite subjective and difficult to quantify; consequently, there is a lack of data of proven value for predicting the need for early intervention. Finally, parental and adolescent preferences often play a role in determining the treatment of varicocele: they may feel that surgery may be of some psychological benefits, restoring normal scrotal appearance and allowing them not to worry about potential future complications.

Techniques of varicocele repair

There are several techniques that can be employed in the treatment of a varicocele, including percutaneous, open, and laparoscopic approaches. With percutaneous techniques, the dilated veins can be sclerosed with a chemical agent or occluded with coils or a balloon. Access can be obtained percutaneously in a retrograde manner via the femoral or jugular vein or in an antegrade manner via the varicocele itself.[201,202] The advantages of the percutaneous techniques include being less costly and having a shorter recovery time compared with open surgery. In older patients, these techniques can be performed under local anesthesia, alleviating the need and risk of general anesthesia. However, it should be noted that in 15–27% of the patients undergoing transvenous occlusion, the procedure could not be performed as a result of difficulties in reaching the varicocele.[203] Potential complications include extravasation of contrast material, coil migration, postprocedure hydrocele formation (11%), and recurrence (5%).

Open surgical correction of varicocele has conventionally been the standard treatment of varicocele for many years. This treatment can be performed inguinally, retroperitoneally, or subinguinally. The Ivanissevich repair utilizes an incision in the inguinal region with the patient in reverse Trendelenburg position. The spermatic cord is exposed and mobilized in the inguinal canal. Under loupe magnification, all veins are ligated. The testicular artery, which may be dilated with warm saline or papaverine and identified visually or with Doppler US, can be spared or mass ligated with the veins. The advantage of this procedure is that it is easy to perform because of its anatomic familiarity and easy access to the cord. With this technique, there is a 3–8.6% incidence of hydrocele postoperatively and a 16% recurrence rate in the treatment of adolescent varicocele. Both the hydrocele rate and the recurrence rate can be reduced using microscopic dissection. Sparing the artery decreases the risk of hydrocele formation by sparing the lymphatic vessels surrounding the artery but increases the risk of recurrence from missed venous connections.

The Palomo technique utilizes a muscle-splitting incision one–two fingerbreaths medial and anterior to the superior iliac crest and the same distance above the estimated position of the internal ring, providing access to the retroperitoneum. The vessels are identified on the posterior aspect of the peritoneum; they may be better visualized by providing traction on the testis. As with the inguinal approach, the testicular artery can be ligated with the vein. The advantages of this technique are that above the inguinal canal there are fewer venous branches requiring ligation and that the vas and its associated vessels have separated from the rest of the cord, minimizing the risk of their injury. However, this approach is often more anatomically difficult and could miss scrotal or pelvic collaterals feeding into the varicocele. The incidence of hydrocele postoperatively is approximately 7%. Similar to that of the Ivanissevich repair, the rate of recurrence is around 11–14% with sparing of the artery or 2% by not sparing of the artery. Several studies[204] have demonstrated that ligation of the artery during Palomo repair can be safely performed and does not result in testicular atrophy.

The subinguinal technique utilizes a low transverse inguinal incision to expose the cord below the external ring. The external oblique aponeurosis is opened and the testis is delivered out of the scrotum. Using an operating microscope, the artery and lymphatic vessels are identified and spared, while all the external spermatic veins and scrotal veins are ligated. By being able to identify and preserve the artery and lymphatic vessels, the incidence of postoperative hydrocele is very low (approximately 0.8%) with a 2.1% recurrence rate.[205]

Over the past decade, the laparoscopic approach to varicocele repair has gained in popularity. It can be performed with a transperitoneal or a preperitoneal approach. For the transperitoneal approach, an incision is made in the umbilicus and is extended down to the midline fascia. A pneumoperitoneum is created with a Veress needle or by the open Hassan technique. The abdomen is insufflated to 12–14 cmH_2O. Two additional ports are placed: one in the midline near the

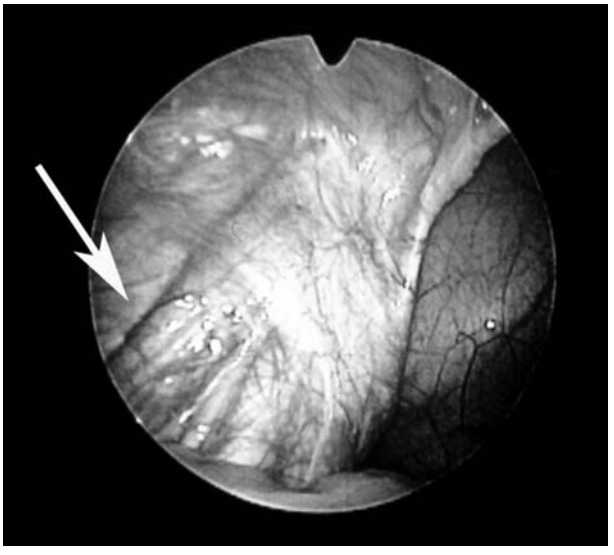

Figure 73.8 On laparoscopy, the spermatic veins (arrow) can be easily identified in the retroperitoneum. Above the level of the internal ring, the vas and its vessels have separated away from the cord, minimizing its injury during the dissection.

pubis and the second in between the other two. The position of the ports should allow the instruments to triangulate the work area. The patient is placed in steep Trendelenburg position to allow the bowel to move out of the pelvis. Collaterals can be accessed by compressing on the main vein and squeezing the testis[206] (Figure 73.8). The vessels are mobilized from the peritoneum and ligated. The artery may be identified with a Doppler US and spared.[207] After the completion of the procedure, the abdominal pressure should be reduced and the area carefully inspected for bleeding. The advantages of this technique include a shorter postoperative convalescence due to avoidance of a larger inguinal or abdominal incisions, better visualization,[208] and the capacity to treat other associated problems such as bilateral varicoceles or concurrent inguinal hernia.[209] The laparoscopic Palomo can be safely performed in patients who have undergone prior inguinal surgery without a risk of testicular atrophy.[210] The disadvantages include the requirement for general anesthesia, the cost, and the potential for bowel injury, bleeding, and peritonitis. Using this technique, the incidence of postoperative hydrocele is approximately 7% and the recurrence rate is 15%.[211–213]

Treatment of postoperative hydrocele and recurrence

Esposito et al[214] observed that the median incidence of postoperative hydrocele after varicocele surgery was about 12%. The incidence is higher after an artery non-sparing vs a sparing procedure (17.6% compared with 4.3%). Interestingly, no difference in postoperative hydrocele rate was observed between those surgeries performed by laparoscopic or by open techniques. Hydroceles are infrequently detected within 6 months of varicocele repair, generally occurring after 6 months up to 3 years following surgery.[215] Total hydrocele regression occurs in approximately 80% of the patients following clinical observation or being treated with simple scrotal puncture.[214] However, some patients may require open hydrocele repair.

Recurrence following varicocele repair is usually noted several months after surgery.[216] A lower recurrence rate is seen when performing mass ligation compared with artery sparing surgery.[204,217] It is uncommon that recurrence is a result of delayed recanalization.[216] Reoperation is indicated when the indications for the original surgery persist. Intraoperative venography may be helpful in defining collaterals that were missed during the initial surgery. This can be accomplished by placing the patient in a reverse Trendelenburg position and making a small scrotal incision to expose the dilated veins. The vein is cannulated with an angiocatheter directed away from the testis. The catheter is then injected with 30% contrast at a volume of 1 ml/kg body weight. After an X-ray is obtained, the vein is flushed with normal saline solution. It is generally recommended that the cord be approached at a higher level in order to ligate the missed collaterals.

Cryptorchidism

74

Thomas F Kolon

Introduction

Cryptorchidism or undescended testes (UDT) is the most common disorder of the male endocrine glands in children. One-third of boys with true cryptorchidism have bilaterally cryptorchid testes, whereas two-thirds are unilateral.[1–3] The main reasons advocated for treatment of cryptorchidism are increased infertility in unilateral and bilateral cryptorchid patients, increased testicular malignancy rate, an increased risk of developing testicular torsion, injury against the pubic bone, and the psychological stigma of an empty scrotum. The current standard of therapy in the United States has been the surgical repositioning of the testis within the scrotal sac (orchidopexy), whereas hormonal manipulation has been more widely used in Europe. However, despite successful relocation of the testis, long-term sequelae of cryptorchidism occur, including infertility, subfertility, and malignancy.

Epidemiology

The incidence of cryptorchidism is reported as being between 3.4% and 5.8% in full-term boys.[1–3] Spontaneous descent may occur in the first 6 months of life. The prevalence decreases to about 0.8% in full-term infants and 10% in preterm infants, and remains there essentially throughout adulthood. A small increase in this prevalence in prepubertal boys (up to 7%) has been reported by several authors and may be due to observer error with retractile testes, testicular ascent, or previously unrecognized UDT in the high scrotal or superficial inguinal pouch regions.[2–6] An increase in UDT has been reported in the United States and South America during the 1970s and 1980s, but since 1985 the rates have stabilized or declined in most countries.[7]

A number of obstetric risk factors have been suggested as possible risk factors for UDT, including advanced maternal age, maternal obesity, breech presentation, cesarean section, low parity, consumption of cola-containing drinks during pregnancy, preterm birth, and low birth weight.[8–11] Furthermore, hypospadias or a family history of cryptorchidism have also been associated with UDT.[12] Infants <900 g have approximately 100% incidence of UDT. This incidence steadily decreases as the birth weight of the infant increases (to 3.3% for 2700–3600 g infants). Similarly, the incidence is 30% for preterm, i.e. <37 weeks estimated gestational age (EGA), compared with 3.4% for full-term boys. The incidence of UDT is also directly related to the position of the meatus in boys with hypospadias. Up to 30% of infants with proximal hypospadias will exhibit concomitant cryptorchidism compared with only 2.5–5% for distal hypospadias. Two-thirds of persistent UDT are unilateral and one-third are bilateral. In boys with unilateral UDT, the right testis is affected twice as often as the left.

Gonadal development

Proliferation and migration of primordial germ cells from the yolk sac into the mesonephric bodies begins in the 4th gestational week. By the 6th week the primordial cell migration from the wall of the embryonic yolk sac along the dorsal mesentery of the hindgut to the genital ridge is completed.[13] These processes accelerate during weeks 5–6, forming the bipotential gonad that replaces the regressing mesonephric body by the end of the 6th week. Development of testicular histology and endocrine function begins during the 7th gestational week and continues into adulthood. It is characterized by four steps in maturation

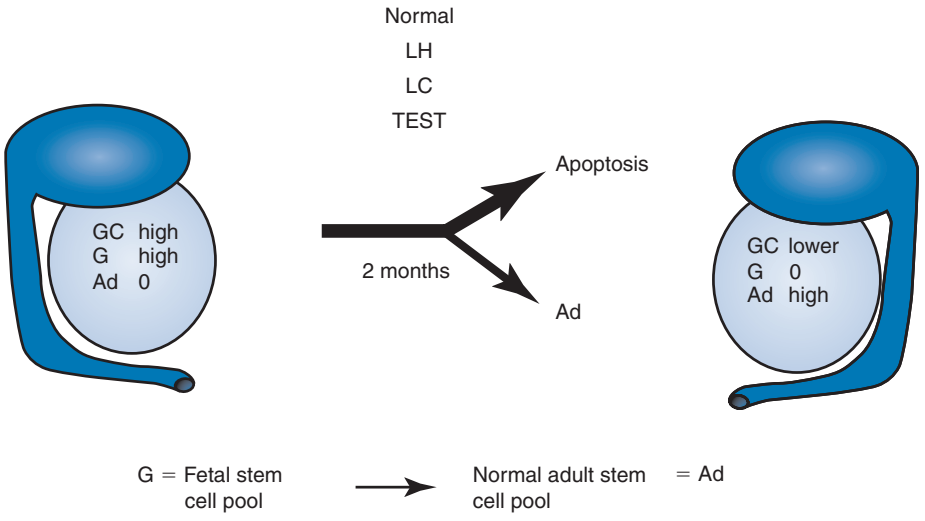

Figure 74.1 Third step in maturation: differentiation of fetal gonocytes into adult dark (Ad) spermatogonia. GC = germ cell, G = gonocyte, LH = luteinizing hormone, LC = Leydig cell, TEST = testosterone.

(two prenatal and two postnatal) prior to the final maturational changes at puberty.

Differentiation of the bipotential gonad into the testis occurs under control of the *SRY* (sex-related gene on the Y chromosome) gene. In the first step in maturation, primordial germ cells enter the emerging testicular cords and differentiate into gonocytes. These gonocytes constitute the fetal stem cell pool of the germ cell line and lie in the center of the testicular cords. Human chorionic gonadotropin (hCG) stimulates fetal Leydig cell development, proliferation, and testosterone secretion. Gonocyte proliferation expands the fetal stem cell pool, whereas fetal Sertoli cells simultaneously differentiate and begin to secrete müllerian inhibiting substance (MIS). Masculinization of the mesonephric (wolffian) duct, paramesonephric (müllerian) duct, and external genitalia begin. MIS causes regression of müllerian structures and testosterone causes development of the wolffian duct to form the epididymis and vas deferens.[14,15]

In the second step in maturation, the level of hCG, number of fetal Leydig cells, and the level of testosterone reach their peaks during the 13th week of gestation. Gonocytes begin to migrate to the basement membranes of the seminiferous tubules and differentiate into fetal spermatogonia. Since they are stem cells, gonocytes can replenish their own numbers. Masculinization of the external genitalia and resorption of the paramesonephric ducts is completed. Maculinization of the mesonephric duct into the epididymis continues and the swelling of the gubernacula begins. Differentiation of fetal spermatogonia continues throughout fetal life. Canalization of the rete testis and mesonephric tubules begins in week 12 and is completed by puberty. Testicular descent occurs in the 7th month of gestation and depends on multiple factors discussed earlier.

The third step occurs postnatally during the 2nd month after birth (Figure 74.1). By now the seminiferous tubules contain numerous germ cells. Approximately half are gonocytes and the rest are fetal spermatogonia. A surge in luteinizing hormone (LH) and follicle-stimulating hormone (FSH) levels stimulates proliferation of fetal Leydig cells, in turn causing a surge in testosterone. Some gonocytes attach to the tubule basement membrane and are transformed. A minority of gonocytes differentiate into adult dark (Ad) spermatogonia, whereas the majority undergo apoptosis and disappear, lowering the total germ cell number. Thus, the gonocyte fetal stem cell pool is replaced by Ad spermatogonia, making up the adult stem cell pool. The transformation and disappearance of gonocytes is normally completed by 6 months of age. The levels of gonadotropins and testosterone fall as fetal Leydig cells regress into inactive juvenile Leydig cells. Some Ad spermatogonia mature into adult pale (Ap) spermatogonia. Fetal Sertoli cells mature into Sa Sertoli cells. This third step is extremely important since the transformation of the fetal stem cell pool into the adult stem cell pool (Ad spermatogonia) is a prerequisite for future maturation of the testis.

At approximately 5 years of age, the fourth important maturational step commences with the onset of meiosis. Simultaneous transient peaks of LH, number and size of juvenile Leydig cells, and testosterone

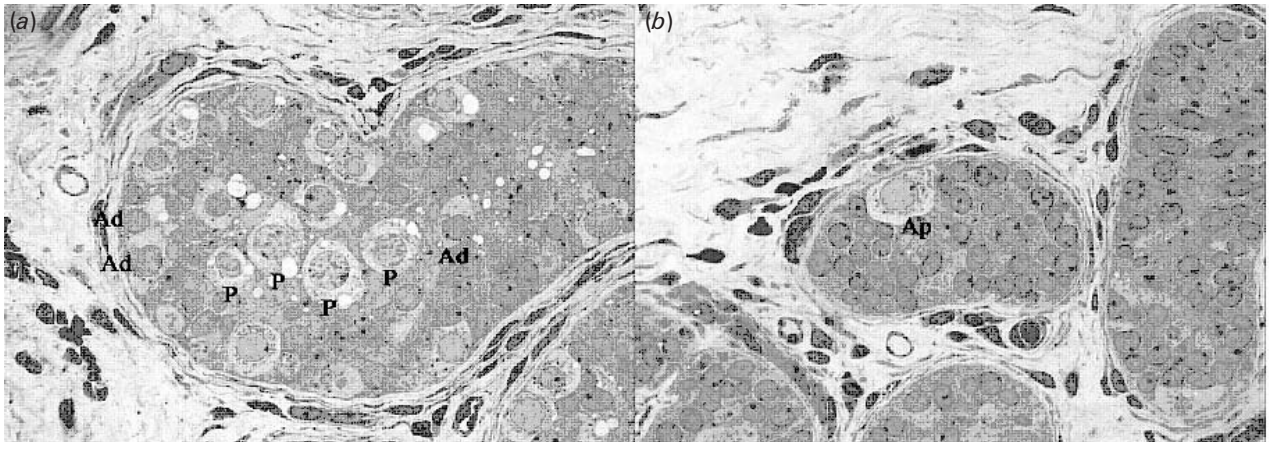

Figure 74.2 (*a*) Descended testis biopsy showing adult dark (Ad) spermatogonia and primary spermatocytes (P). (*b*) Cryptorchid testis biopsy showing paucity of Ad spermatogonia and persistence of fetal gonocytes with an adult pale (Ap) spermatogonium.

occur. The increased testosterone stimulates an increase in Ad spermatogonia and the total germ cells. It also triggers the maturation of the mitotic Ad spermatogonia into primary spermatocytes that are germ cells in prophase of the first meiotic division. Sa Sertoli cells mature into Sb Sertoli cells.

Final germ cell maturation at puberty depends on adequate completion of the two prepubertal developmental milestones. The pubertal surge in LH and FSH stimulates the inactive juvenile Leydig cells to multiply and mature into adult Leydig cells. They produce the high pubertal surge in testosterone that triggers the final maturation to secondary spermatocytes, early and late spermatids, and sperm. Sertoli cells undergo their final maturation into Sc Sertoli cells. Complete spermatogenesis is usually accomplished by 13–15 years of age.

In the cryptorchid testis, the number of Leydig cells is decreased and they appear atrophic (Figure 74.2). In the first 6 months of life, the total number of germ cells is within the normal range in cryptorchid testes; however, the number of spermatogonia remains low and does not increase with age. This gives evidence for the lack of transformation of gonocytes into Ad spermatogonia in the cryptorchid testis. The normal postnatal development of Leydig cells and germ cell transformation parallels the normal gonadotropin and resultant testosterone surge around 60–90 days of life.[16]

Etiology

Despite the relatively frequent incidence of cryptorchidism, the etiology and molecular markers of future fertility or malignancy remain obscure.[13] Cryptorchidism is a well-known manifestation of chromosomal abnormalities and a common component of over 50 syndromes of multiple congenital anomalies.[17] Cryptorchidism, when associated with other congenital anomalies like hypospadias, has a higher incidence of chromosomal anomalies (12–25%) than when it occurs as an isolated defect (3–4%).[18–21] However, at present, there is no consistent chromosomal disorder associated with isolated cryptorchidism.

Cryptorchidism accompanies defects in every intrinsic step of the hypothalamic–pituitary–testicular–end organ axis as well as defects in extrinsic pathways that affect the axis such as extratesticular cholesterol synthesis, adrenal steroidogenesis, placental 'insufficiency', and maternal or environmental endocrine disruptors. Hypogonadism results from defects in the hypothalamic–pituitary–testicular axis and is characterized by cryptorchidism, hypospadias, small penis, chordee, minor scrotal anomalies, inguinal hernia, hydrocele, and epididymal anomalies. Huff et al proposed a cryptorchidism sequence, since over 70% of examined cryptorchid boys had one or more of these late defects of masculinization associated with the endocrinopathy of hypogonadism. He classifies the multiple conditions upstream from cryptorchidism into errors of blastogenesis, organogenesis, sexual differentiation, and late masculinization; the cascade of events downstream from cryptorchidism are testicular atrophy, microlithiasis, intrauterine torsion, Sertoli cell nodules, and, most importantly, germ cell maldevelopment. The abnormal proliferation and maturation of germ cells in

cryptorchidism leads to an overall decrease in total germ cell counts and loss of the adult stem cell population. These alterations in germ cell maturation and proliferation produce the most important tertiary abnormalities of the sequence: subfertility and testicular neoplasia.[22]

Several case series of the familial occurrence of cryptorchidism have demonstrated that a heritable component exists.[23–27] Furthermore, large epidemiologic studies have shown a consistent pattern of inheritance for isolated cryptorchidism. Of boys with UDT, 4.0% of their fathers and 6.2–9.8% of their brothers also had undescended testes.[2,3,28] Elert et al conducted a study to examine the frequency of a positive family history and to calculate the risk for the newborn male boys to have an UDT. They concluded an overall risk of 3.6-fold over the general population, if a family member was affected.[29] This compares with a 1–3% incidence of cryptorchidism in the general population.[1] These inheritance patterns are consistent with a multifactorial etiology of cryptorchidism. Based on murine gene knockout models, some of the candidate genes involved in cryptorchidism are homeobox (*HOX*), calcitonin gene-related peptide (*CGRP*), insulin-like hormone (*INSL3*), G-protein-coupled receptor affecting testis descent (*LGR8* or *GREAT*), androgen receptor (*AR*), and the estrogen receptor 1 (*ESR1*) genes.

Androgen influence

Hutson has proposed that testicular descent occurs in two phases. The initial transabdominal aspect may be controlled by MIS.[30] The inguinoscrotal descent appears to be androgen-dependent and is mediated indirectly through the release of CGRP. Androgens act on the genitofemoral nerve (GFN), which is sexually dimorphic and releases CGRP upon stimulation, producing rhythmic contractions of the murine gubernaculum. Hutson et al found two rodent models of cryptorchidism to have deficiencies of CGRP in the GFN (the tfem mouse and the rat prenatally exposed to antiandrogen). Alternatively, Huff has proposed that there is only a transinguinal phase of testis descent; this is based on a pathologic examination of human fetal specimens at the Carnegie Collection of Human Embryos.[31] After gonadal formation, the formerly suggested 'transabdominal migration' is actually a single position where the abdominal testis 'appears to descend' due to the unfolding of the human embryo around 8–9 weeks of gestation, as it moves from the embryonic to the fetal stage of development.

Inguinoscrotal descent is blocked in mice with complete androgen resistance (testicular feminization) where the *AR* gene has been knocked out.[30,32] Deletions and mutations may cause structural changes in the *AR*, altering its function.[33] Up to 50–70% of male pseudohermaphroditism, which includes hypospadias and cryptorchidism, is due to *AR* gene disorders (androgen insensitivity syndrome – AIS), which suggests a role for androgens in this developmental process.[34,35] The majority of *AR* gene mutations identified are in the DNA-binding (exons 2–3) and ligand-binding (exons 5–8) domains. However, the same mutation can result in a different or even a normal phenotype in members of the same family.[36,37] It appears that phenotypic variations in families affected by partial AIS are modulated by factors other than or in addition to point mutations of the *AR* gene. Furthermore, the role of the *AR* gene mutations in isolated forms of hypospadias or cryptorchidism is unclear. It is a definite yet uncommon cause of hypospadias, but has not yet been identified in isolated cryptorchidism.[21,38–40]

Exon 1 of the *AR* gene contains the transactivation domain and encodes polymorphic glutamine (CAG) repetitive sequences. The CAG repeat length ranges from about 15 to 30 units in controls, exhibiting ethnic variability.[41] Within this spectrum, the CAG length influences AR function, providing enhanced androgen action with a shorter repeat length and decreased function with a longer length.[42] Mutations in a series of cytosine–adenosine–guanine (CAG) trinucleotide repeat sequences located at a polymorphic region in exon 1 of the *AR* gene have been linked to an X-linked neuromuscular disease termed spinal bulbar muscular atrophy or Kennedy's disease.[43] These affected men display subtle signs of androgen resistance such as gynecomastia, testicular atrophy, and reduced fertility. Increased AR CAG length has also been related to male infertility through defective spermatogenesis, although others have found conflicting results.[44–46] Within the normal polymorphic range, an expansion of the CAG tract decreases the AR activity and may be associated with cryptorchidism and/or infertility. Casella et al have seen an increased CAG length when both cryptorchidism and hypospadias are present.[26] Ogata et al reported an abnormally expanded CAG length in a boy with undermasculinized genitalia, but later concluded that CAG expansion is not likely to be a major cause of cryptorchidism.[47,48] Ferlin et al analyzed CAG and GGC exon 1 repeat lengths in 105 formerly cryptorchid men compared with 115 fertile non-

cryptorchid men.[49] No difference was found when considered separately but some combinations of repeat lengths are significantly more frequent in men with bilateral UDT in a manner similar to findings in idiopathic infertile males.

Estrogen influence

The *ESR1* gene is a potentially important candidate gene for UDT. Yoshida et al performed *ESR1* analysis in 63 cryptorchid boys and 47 controls by screening 30 single nucleotide polymorphisms (SNP) in the gene.[50] They found a significantly higher polymorphism frequency of an AGATA haplotype within the intron in cases vs in controls (34% vs 21%), and the association of the haplotype with UDT was significant in a recessive mode ($p = 0.006$). The investigators speculate that this SNP enhances *ESR1* signaling. Thus, excessive estrogenic effects may decrease expression of INSL3 in Leydig cells, affecting the development of the gubernaculum, and therefore, testicular descent. Furthermore, excessive estrogenic signaling may suppress gonadotropin production and the steroidogenic capacity of Leydig cells, resulting in androgen deficiency. Fetuses with excessive estrogen exposure, owing to allelic variants in the *ESR1* gene, as well as reduced testosterone levels, owing to in-utero exposure to phthalates, might have elevated estrogen:androgen ratios and be at risk for developing UDT.

INSL3/GREAT genes

Several investigators have examined the role of Leydig insulin-like hormone as a putative trophic hormone of the first part of testicular descent. It is a member of the insulin hormone superfamily and is expressed in the developing testis. Mice mutant for *Insl3* are viable but exhibit bilateral cryptorchidism.[25,51,52] These mice have developmental abnormalities of the gubernaculum and abnormal spermatogenesis and infertility. However, in a manner similar to the *AR* gene, mutations of the *INSL3* gene in humans are infrequent.[53–55] The *GREAT* gene is also highly expressed in the gubernaculum. Mutations in this gene have been associated with cryptorchidism in the mouse and rarely in the human.[56,57] The ligand for the *GREAT* gene has been identified as the INSL3 peptide.[58–60] Screening of approximately 700 patients with UDT for allelic variants in *INSL3* yielded several mutations, only one of which (P49S) reduced INSL3 binding to GREAT.[61] Mutation analysis of the *GREAT* gene revealed a single mutant T222P allele found in 3% of patients and no controls.[57–60] The mutant allele produces a non-functional receptor unable to respond to ligand stimulation in vitro.[57] Thus, in some patients it appears that an abnormal gubernaculum plays a role in the testicular maldescent. These genes may work in concert to help control testis development and migration, but mutations involving these two genes do not represent a frequent cause of UDT in humans.

Homeobox genes

Homeobox (*HOX*) genes play a key role in the morphogenesis of segmental structures along the anterior–posterior body axis.[62] These genes act as master regulatory switches or transcription factors that specify axial identity and control the growth and differentiation of cells related by position. Murine *hoxa10* knockout male mice exhibited bilateral cryptorchidism with developmental abnormalities of the gubernaculum and resultant abnormal spermatogenesis and infertility.[63,64] Similarly, mice homozygous for *hoxa11* deletions are also infertile and cryptorchid.[27,65] Hormonal disruption was probably not the cause of UDT in these knockout mice, as they appeared normally masculinized. In-situ hybridization for *hoxa10* transcripts in wild-type mice indicate this gene is expressed in the gubernacular cord and bulb, but not in other tissue of the male reproductive tract.[63] Branford et al[64] found that the reproductive tracts of *hoxa10* or *hoxa11* single heterozygous mutants were normal but male transheterozygotes (*hoxa10±* and *hoxa11±*) displayed UDT and twisting of the ductus deferens, similar to what is seen with the knockouts of these genes. *Hoxa10* and *hoxa11* appear to be functionally redundant in the development of the male reproductive tract, such that a quantitative loss of any two *hoxa10*/*hoxa11* alleles results in similar anomalies.

Several human studies have been conducted to evaluate the association between allelic variants in *HOX* genes and UDT. Allelic variants in exons 1 and 2 of the *HOXA10* gene were evaluated in 16 controls and 45 cases with UDT by Kolon et al.[24] In exon 1 of *HOXA10*, five missense mutations were found in five cases and one large deletion in another case out of 45 boys studied, a statistically significant elevation in allelic variants in the UDT group compared with the controls. In a smaller study, Bertini et al[66] examined exons 1 and 2 of *HOXA10* for allelic variants in 18 patients with UDT and 28 healthy controls. The same allelic variant was detected at similar levels in cases

and controls. Further evaluation should be carried out to fully characterize the role of these posterior *HOX* genes in abnormal testicular descent. Many other gene products have been targeted as being expressed in testicular differentiation (i.e. *PAX5*, *SRY*, *SOX9*, *DAX1*, *MIS*) but not specifically in cryptorchidism.[67,68]

Hormonal factors

It has been theorized that this spontaneous descent in infancy may occur as a result of the normal gonadotropin surge that occurs around 60–90 days of life.[69–72] Gendrel et al and Job et al reported blunting of this surge in boys with UDT that remain undescended in the first year of life.[69,70] They demonstrated a significant difference in the polynomial regression curves comparing the testosterone levels of persistently cryptorchid testes with those having delayed spontaneous descent. However, the positive predictive value that bilateral UDT will have abnormally low testosterone levels is only about 23%.[69] In contrast, Barthold et al examined gonadotropin and testosterone, estradiol, inhibin B, leptin, and sex hormone-binding globulin in a cohort of cryptorchid boys. They failed to identify any significant differences in hormonal levels in their cohort compared with controls.[73]

An endocrine disruptor is an environmental chemical that interferes with the production, transport, and metabolism of hormones in the body.[74] Some of these agents have estrogenic activity, whereas others act as agonists and antagonists of androgens.[74,75] Endocrine disruptors have been hypothesized to play a role in cryptorchidism, as androgens contribute significantly in the physiology of germ cell development and testicular descent. Several environmental chemicals have antiandrogenic effects in rodent models. Although these agents act by many different mechanisms, they all produce similar effects on the developing male reproductive tract. At high in-utero doses, antiandrogens are associated with UDT and agenesis of the epididymis, whereas at lower doses hypospadias and decreased anogenital distances are seen. Boys exposed to the antiandrogenic effects of diethylstilbesterol in utero have an increased number of genital abnormalities, including cryptorchidism.[76] Phthalate esters inhibit testosterone synthesis during fetal life and produce dose-related abnormalities of the male reproductive tract such as focal hyperplasia of fetal Leydig cells that persists postnatally, as well as agenesis of the gubernaculum.[77–80] In animal models, phthalates reduce cholesterol transport across the mitochondrial membrane, decrease testosterone biosynthesis, and reduce expression of the *insl3* gene.[81,82] Animal research findings demonstrate a coordinated, dose-dependent reduction in expression of key genes involved in cholesterol transport and steroidogenesis, and a corresponding reduction in testosterone in fetal testes at low dibutyl phthalate (DBP) doses which do not produce male reproductive tract anomalies.[77] Similar studies have been carried out in adult rats to determine the pattern of gene expression in the proximal wolffian duct, which gives rise to the epididymis, following prenatal exposure to DBP. Changes in mRNA expression were observed in genes involved in testosterone biosynthesis and testicular descent, including the insulin-like growth factor pathway and the androgen receptor.[83] These alterations in expression of genes at phthalate doses that do not produce isolated UDT suggest that gene–environment interactions could occur in human populations. It has been hypothesized that fetuses with susceptible genotypes exposed in utero to environmentally relevant doses of phthalates may be at the greatest risk for developing UDT. Findings with the phthalates are of particular concern because exposure is ubiquitous and phthalates are widely used in many consumer products. The phthalate monoester metabolites have been found in the urine samples of >75% of approximately 2550 participants in the 1999–2000 National Health and Nutrition Examination Survey (NHANES).[84,85] Familial clustering of hypospadias and UDT among first-degree relatives has been suggested as evidence for a genetic component for these anomalies. However, another etiologic possibility is the role of exposure to environmental contaminants in familial clusters because of the high probability of shared exposures among first-degree relatives.[86]

These animal findings further advocate a multifactorial and complex etiology of cryptorchidism. UDT is a variable and multifactorial phenotypic trait that probably involves several candidate genes as well as clinical (hormonal) and environmental risk factors rather than a causative single gene mutation. It is likely that a shift in the dynamic equilibrium of these factors is involved.

Other factors

Secondary cryptorchidism can occur after inguinal surgery, either as a result of scar tissue or the difficulty in diagnosing UDT in a young boy with a hernia. An

ascending testis is one that appeared descended at birth and later ascended. Reports suggest that an ascending testis has similar testis biopsy histology to a UDT.[87] Yearly examination should occur in questionable cases to identify a true UDT.

Diagnosis

History and physical examination

A thorough history should include prematurity (incidence of UDT in premature boys is as high as 30%), maternal use/exposure to exogenous hormones (estrogens), lesions of the central nervous system (myelomeningocele), and previous inguinal surgery. Document a family history of cryptorchidism and other congenital anomalies, neonatal deaths, precocious puberty, infertility, and consanguinity. It is also important to know if the testes were ever palpable in the scrotum at the time of birth or within the first year of life. Testicular retraction, due to a strong cremasteric reflex, is most apparent between 4 and 6 years of age and may lead to an inaccurate diagnosis of UDT.[16]

An undescended testis can be classified by its location. It may be located in the abdomen, the inguinal canal, the superficial inguinal pouch, the upper scrotum, or rarely ectopic (perineum, contralateral scrotum, or femoral). However, for treatment purposes, the main distinction that needs to be made is whether or not the testis is palpable.

The patient should be examined supine in the frog-leg position with both legs free. With warmed hands, check the size, location, and texture of the contralateral descended testis (CDT). Begin examination of the UDT at the anterior superior iliac spine and sweep the groin from lateral to medial with the non-dominant hand. Once the testis is palpated, grasp it with the dominant hand and continue to sweep the testis toward the scrotum with the other hand. With a combination of sweeping and pulling, it is sometimes possible to bring the testis to the scrotum. Maintain the position of the testis in the scrotum for a minute, so that the cremaster muscle is fatigued. Release the testis and, if it remains in place, it is a retractile testis. If it immediately pops back to a prescrotal position, it is a UDT.

For the difficult-to-examine patient (chubby 6 month-olds or obese youths), the sitting cross-legged position or the baseball 'catcher's position' can also help relax the cremaster muscle. Wetting the fingers of the non-dominant hand with lubricating jelly or soap can increase the sensitivity of the fingers in palpating the small, mobile testis.

A retractile testis is often confused with a UDT. The key to distinguishing a retractile testis from a UDT is demonstrating that the testis can be delivered into the scrotum. The retractile testis will stay in the scrotum after the cremaster muscle has been overstretched, whereas the low UDT will immediately pop back to its undescended position after being released. If there is any question, the child should be seen in follow-up for a repeat examination. Miller et al have also recommended the use of hCG stimulation to help distinguish between a retractile and an undescended testis in the hard-to-examine child.[88]

An atrophic or vanishing testis can be found anywhere along the normal path to the scrotum. The etiology is thought to be due to neonatal vascular ischemia, possibly due to torsion.[89] The CDT may be hypertrophied in these boys, but this is not a reliable diagnostic sign.

Upon surgical exploration, 60–80% of non-palpable testes are present in the inguinal canal or in the intra-abdominal location, whereas up to 40% are absent or an inguinoscrotal nubbin of fibrous tissue and hemosiderin. Presence of bilateral UDT should raise suspicion of an endocrine disorder or an intersex state that should be evaluated. Cryptorchidism associated with hypospadias, especially proximal, should also raise the possibility of the intersex state and occurs in 30–40% of the patients, mainly consisting of defects in the testosterone synthesis pathway.[90]

Laboratory tests

In boys with unilateral or bilateral UDT where one testis is palpable, no further laboratory evaluation is necessary to aid the diagnosis. In boys with bilateral UDT where neither testis is palpable and also in boys with associated hypospadias, chromosomal and endocrinologic evaluation may be carried out but is not always necessary.[19] These levels should be drawn during the maternal newborn gonadotropin surge or at 60–90 days of life. In patients ≤ 3 months with bilateral non-palpable UDT, LH, FSH, and testosterone levels will help determine whether the testes are present; >3 months of age, an hCG stimulation test will aid in the diagnosis of the absent testes. A weight-based single injection of hCG (100 IU/kg) is usually sufficient to detect a rise in serum testosterone 4–5 days later.[91] A failure to see a measurable increase in testosterone in combination with elevated LH and

FSH is consistent with the diagnosis of anorchia.[92,93] Müllerian inhibiting substance may be a more sensitive and specific prepubertal marker for detecting the presence of testes. Lee et al found that serum MIS correlates with testicular tissue. A measurable value is predictive of non-palpable UDT, whereas an undetectable value is highly suggestive of anorchia but warrants further investigation such as hCG stimulation.[94] Both MIS and testosterone levels may be misleading in cases of UDT with intersex if the testes are severely dysgenetic or if there is a mutation of the antimüllerian hormone or receptor genes.

Imaging

Ultrasound, a computed tomography (CT) scan, and magnetic resonance imaging (MRI) can detect testes in the inguinal region, but this is also the region where they are easily palpable. The accuracy of ultrasound and CT falls to 0–50% in showing intra-abdominal testes in various series.[95] Hrebinko and Bellinger found that the most reliable mode of examination was the physical examination by a pediatric urologist (84%) compared with a referring physician (53%).[95] The accuracy of the radiologic examination was 44% and the study did not influence the management decision in any of the cases. However, Yeung et al employed gadolinium-enhanced magnetic resonance angiography (MRA) to identify 100% of canalicular UDT and 96% of intra-abdominal UDT (one missed vanishing testis).[96] Eggener et al performed a hypothetical protocol of MRA with observation of testicular nubbins and nearly one-third of the boys avoided surgery without any increased cost of care.[97] Although MRA is currently expensive and requires sedation, it may prove to be the best diagnostic tool. Clearly this technique requires further prospective evaluation. Currently, for non-palpable testes, examination under anesthesia, open inguinal exploration, or laparoscopy is necessary to confirm the presence of testes.

Treatment

Hormonal therapy

Primary hormonal therapy with hCG or gonadotropin-releasing hormone (GnRH) or LHRH (LH-releasing hormone) has been used for many years, especially in Europe. The action of hCG is virtually identical to that of pituitary LH, although hCG appears to have a small degree of FSH activity as well. It stimulates production of gonadal steroid hormones by stimulating the Leydig cells to produce androgens. The exact mechanism of action of the increased androgens in testicular descent is not known but it may involve effects on the testicular cord or cremaster muscle. This medication is administered by intramuscular injection. Multiple series have been published, but because of differences in patient age, treatment schedules, and possible inclusion of retractile testes, very divergent results have been reported.

Many dosage schedules are reported, ranging from 3 to 15 doses.[98–100] However, hCG appears to be as effective in 3 or 4 doses vs 9 or 10 doses. One of the most common schedules is 250 IU/dose in young infants, 500 IU/dose up to 6 years old, and 1000 IU/dose greater than 6 years given twice a week for 5 weeks (International Health Foundation). Success rates for descent into the scrotum are 25–55% in uncontrolled studies, but only 6–21% in randomized, blinded studies. Distal inguinal testes in older boys are more likely to descend in response to hormonal treatment than abdominal testes. Repeated courses have offered little advantage. Side effects of hCG treatment include increased scrotal rugae, pigmentation, pubic hair, and penile growth, which regress after treatment cessation. A total dose of more than 15 000 IU must be avoided, since it may induce epiphyseal plate fusion and retard future somatic growth.

Agonistic analogues of GnRH, such as nafarelin or buserelin, stimulate the release of the pituitary gonadotropins LH and FSH, resulting in a temporary increase of gonadal steroidogenesis. Repeated dosing abolishes the stimulatory effect on the pituitary gland and twice-daily administration leads to decreased secretion of gonadal steroids by 4 weeks. These hormones are available as a nasal spray but are only approved for the treatment of cryptorchidism in Europe. Interpretation of results is again tainted by multiple treatment strategies. Success rates in uncontrolled studies range from 13 to 78%, whereas better-controlled investigations resulted in 6–38%.[101,102] Rajfer et al conducted a randomized, double-blind study comparing hCG 3300 IU/week for 4 weeks with GnRH spray 200 μg six times a day for 4 weeks. Descent into the scrotum occurred in 6% of the hCG group and in 19% of the GnRH group.[100] Several authors have recommended combined GnRH–hCG hormonal treatment. Lala et al administered LHRH 1.2 mg/day for 4 weeks and non-responders also received hCG 500 IU three times a week for 3 weeks. After combined treatment, 38% of testes descended.[102] Bica and Hadziselimovic treated patients with a low dose of buserelin 20 μg as a daily

spray for 28 days followed by hCG for failures; 26% of the testes descended with the spray alone, while hCG increased the descent to 37%.[103] Hadziselimovic et al advocated initial treatment with GnRH spray 400 μg three times a day into each nostril for 4 weeks followed by salvage treatment for failures with hCG 1500 IU/week for 3 weeks. A success rate of 56% with GnRH was increased to 65% with the addition of hCG.[104]

The recognized side effects of increased androgens, including increased penile or testicular size, scrotal erythema, or erections, seem to be less with GnRH than hCG. Initial treatment with GnRH may deserve some consideration since it is administered as a spray rather than an injection. Even in 20% of patients, it may aid descent in more distal testes, make intra-abdominal testes palpable, or help differentiate retractile from true undescended testes. Hormonal therapy may also have prophylactic value.[105] It has been shown that use of an LHRH analogue in boys with very severe histologic changes in the testis – total germ cell count <0.2 germ cells/tubule in UDT and <0.6 germ cells/tubule in CDT – has an advantageous effect on the developing germ cells. In a study by Huff et al, patients who had no germ cell count on the biopsy did not show improvement after hormonal therapy but those who had some germ cells demonstrated improvement.[106] This improvement in germ cell count and maturation may eventually reflect a better prognosis for fertility. Furthermore, Hadziselimovic and Herzog showed that men who were treated in childhood with hormones had better semen analyses than men who had childhood orchidopexy alone or placebo treatment.[107]

Long-term prognosis

Patients with cryptorchidism have two major concerns: they have an increased incidence of developing testicular cancer and also a heightened risk of subfertility.[108–110]

Testicular malignancy

Cryptorchidism has been positively related to testicular cancer but the increased incidence of malignancy in cryptorchid testes varies from 49/100 000 (0.05%) to 12/1075 (1%).[110,111] Early reports stated a significantly higher risk of carcinoma in an abdominal testis; however, inclusion of boys with abnormal karyotypes or genitalia may have skewed the results.[112,113] Although one postulate is that the etiology of the testicular cancer is related to the abnormal position of the testis, the mild increase in cancer in the contralateral descended male argues for an intrinsic testicular abnormality as the cause. The increase in incidence of malignancy in cryptorchid testis warrants close follow-up, especially after puberty. Every cryptorchid boy should be taught how to perform a monthly testicular self-examination in order to try to enable early detection. Parents should be made aware of the fact that orchidopexy does not necessarily decrease the risk for testicular cancer.

Fertility

Formerly bilaterally cryptorchid men have greatly reduced fertility compared with unilateral cryptorchids and the general male population. Lee et al showed a paternity rate of 62% (38% infertile) in formerly bilaterally cryptorchid men compared with a matched control group of 94% (6% infertile), indicating a six times increased risk.[114] In contrast, unilaterally cryptorchid men had a paternity rate of 89.5%. Although this represents a twofold increase in infertility, this rate is similar to the level of infertility found in other studies of the general population. Examination of subfertility, or time to pregnancy, shows that bilaterally cryptorchid men have greatly increased waiting times to pregnancy (33.9 months compared with 11.1 months for unilaterals and controls). Lee et al also examined the association of pretreatment testis location with fertility rates and various hormone levels (inhibin B, LH, FSH, testosterone) in adulthood.[115] They concluded that 'preoperative testis location in men with previous unilateral cryptorchidism is not a major determinant of fertility according to paternity, sperm count, or hormone levels.' A prepubertal Ad spermatogonia count or other as yet unidentified molecular markers may be more useful indicators of fertility (and paternity) in these patients. Further investigation is needed concerning sperm motility, morphology, and function.

Summary

Research efforts to define the pathophysiology of cryptorchidism and its sequelae have rapidly advanced in the past 10 years. Surgical techniques have been so refined that today 6-month-old cryptorchid boys are repaired with great success. Further studies will be aimed at identifying those boys that are at increased risk for future infertility or malignancy in order to intervene early and change their outcome.

Surgical management of the undescended testis

75

Israel Franco

Introduction

The undescended testis is commonly encountered in the general practice of urology and pediatrics, whereas the non-palpable testis accounts for 20% of all undescended testes. Testes may be non-palpable when they are intracanalicular and never emerge beyond the external ring or when they are located intra-abdominally; they can also be atrophic, dysgenetic, or absent (Table 75.1).[1]

The best time to make the diagnosis of an undescended testis is in the newborn, since the cremasteric reflex is absent or significantly diminished early on in life. The absence of large amounts of fat makes it easier to feel a testis at this time. The vast majority of testes that have not descended by 3–6 months of age in full-term infants are unlikely to descend spontaneously. Wenzler et al[2] have shown that only 6.9% of all undescended testes seen before 1 year of age will spontaneously descend. Of this group, none descended after the child was 6 months of age. Spontaneous descent is possible in the premature infant until 3 months after term, so final judgment in premature infants should be postponed accordingly.

Of greater significance is the child who is monorchid or anorchid. They account for 33–45% of all children with non-palpable undescended testes.[3] Proper diagnosis of this condition is essential for parent and child to make sure adequate protection is

afforded to the remaining testis. Monorchidism is most frequently due to in-utero torsion (IUT) or vascular accidents that occur during development and descent of the testis. True testicular agenesis is rare. Bilateral IUT or anorchia is also quite rare. It has been reported to occur in 0.6% of 5815 children and is estimated to occur in 1 of every 20 000 boys (Table 75.2).[1,4]

Evaluation of the non-palpable testis

The best tool to evaluate the non-palpable testis is a thorough physical examination in a calm child. Ultrasound generally adds little to the evaluation in most instances. In an obese boy it is not unusual to not be able to palpate a testis that is sitting in the superficial inguinal pouch, and this is one instance where ultrasound can be helpful. If nothing is clearly palpable, palpation over the pubic tubercle can reveal cord structures. The expression of pain during examination can be a reliable indicator of the presence of a testis in this area.

Palpation of the scrotum is critical in that almost all atrophic testes lie either in the scrotum or its upper recesses.[5–7] These nubbins are generally firm and pea sized and can be mistaken for fat and vice versa.

The size of the contralateral testis is a useful adjunct to the evaluation of the non-palpable testis. This was first described by Koff in 1991.[8] Unfortunately, there is quite a bit of overlap, making this an unreliable indicator of the need for exploration. This was confirmed by Huff et al[9] in 1992, who noted a wide range in standard deviations from 27 to 74% in testis size, even though there was a statistically significant difference in size. Their conclusion was that the volume of the contralateral testis is not a reliable criterion for differentiating an absent testis from an intra-abdominal testis. Hurwitz and Kaptein[10] set about reproducing Koff's study, but this time they lowered the length of the solitary testis to 1.8 cm and found that in boys with unilateral non-palpable testis without contralateral enlargement only 50% were monorchid. It seems that some of the atrophic testes are larger, and might inhibit hypertrophy of the contralateral testis. The larger atrophic remnants can be predicted laparoscopically by the presence of a more prominent vessel noted entering the canal (Figure 75.1). Some undescended testes may produce less testosterone than the normal testis, leading to hypertrophy of the contralateral testis; thus, in all cases, one should proceed to orchidopexy or removal of the nubbin.

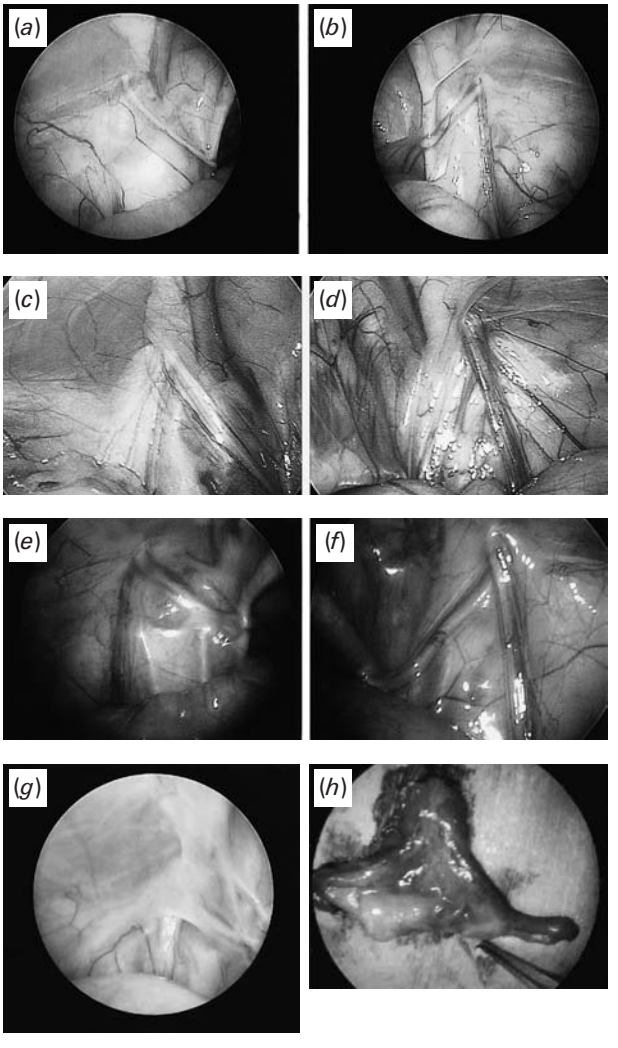

Figure 75.1 Different appearances of internal ring in suspected in utero torsion (IUT). (*a*) Classical IUT with complete atrophy of vessels and resultant absent or small testicular remnant. (*b*) Normal appearance of the contralateral ring. (*c*) IUT with thin vessels. (*d*) Normal contralateral side. (*e*) IUT typically seen with larger remnants. (*f*) Normal contralateral side of (*e*). (*g*) Ring of suspected atrophic testis found on examination. The ring was closed but dimpling of the ring by invagination of the processus vaginalis is indicative that this is not atrophy. (*h*) A small dysmorphic testis was found in the groin.

Radiologic evaluation for the non-palpable testis

Numerous techniques have been described to identify intra-abdominal testes. Pneumoperitoneography utilizing nitrous oxide,[11] contrast peritoneography,[12] aortography, selective angiography, and spermatic venography have all had their proponents.[13–16] Except in planning for autotransplantation, routine

perioperative laparoscopy has supplanted all invasive testing for the non-palpable testis. Ultrasonography,[17–21] computed tomography (CT) scanning,[22] and magnetic resonance imaging (MRI)[23–26] have had limited success. Gadolinium-infusion magnetic resonance angiography (MRA) has had a reported success rates of 100% in a small study involving 17 non-palpable testes.[27] Yeung et al[28] reported a high success rate in 22 of 23 patients in which either a testis or nubbin was found utilizing this technique; the one missed case was a vanishing intra-abdominal testis. This is an encouraging result, but more reports of this technique will be necessary to verify its accuracy.

The role of human chorionic gonadotropin administration for the non-palpable testis

Numerous reports of the beneficial effects of human chorionic gonadotropin (hCG) stimulation leading to partial descent of an intra-abdominal testis have been published. This was noted in the Polascik et al[29] study in which 90% of viable testes descended to a palpable position, although 61% of the children still had non-palpable testes that required exploration. Theoretically, this should obviate the need for laparoscopy if the testis is now palpable. Unfortunately, complete descent is only achieved in 2% of boys with an intra-abdominal testis.

hCG stimulation has been said to have beneficial effects on testicular vasculature and to improve survival of the testis after orchidopexy. There are, however,[30] inflammatory changes in the testis seen after hCG stimulation that might be beneficial or detrimental. The fact remains that there are no controlled studies that support the contention that hCG stimulation improves the outcome of orchidopexy.

Diagnostic surgical approach to the non-palpable testis

Scrotal exploration for the management of the unilateral non-palpable testis

Traditionally, the non-palpable testis has been explored via a groin incision.[31] With the advent of laparoscopy and the recognition that the majority of testicular remnants are found below the level of the external ring, there has been a push to perform scrotal exploration first to obviate the need for a groin incision. The data are now quite convincing that the majority of testicular nubbins are easily removed via this route; this accounts for 32–62% of boys with unilateral non-palpable testis.[7] Belman and Rushton[5] have championed initial scrotal exploration and reserving laparoscopy for patients in whom testicular remnants are not found or in those who have a patent processus vaginalis. It is the author's opinion that the only definitive sign of a true nubbin is greenish-brown discoloration associated with hemosiderin. This can be used as confirmation that the tissue that is being removed is truly the product of a torsion episode. If the surgeon does not identify the greenish-brown color of hemosiderin, then laparoscopy or groin exploration should be considered (see Figure 75.1a,c,e).

Whether nubbins need to be found and removed is cause for debate. Plotzker[32] reported viable tubular tissue in 3 of 23 nubbins removed at surgery. In the author's series,[3] 6 of 50 nubbins had viable testicular tissue. Cendron et al[33] calculate a risk of 0–1.1% of cancer developing in these nubbins. This is based on finding no viable testicular tissue in these nubbins in a small series of 29 specimens. It has been our personal experience that the vast majority of the nubbins are in the scrotum when found. Therefore, if by inference these testes are not undescended, then theoretically they are normal testis with no greater risk for malignancy than the contralateral side.

The role of laparoscopy in the evaluation of the non-palpable testis

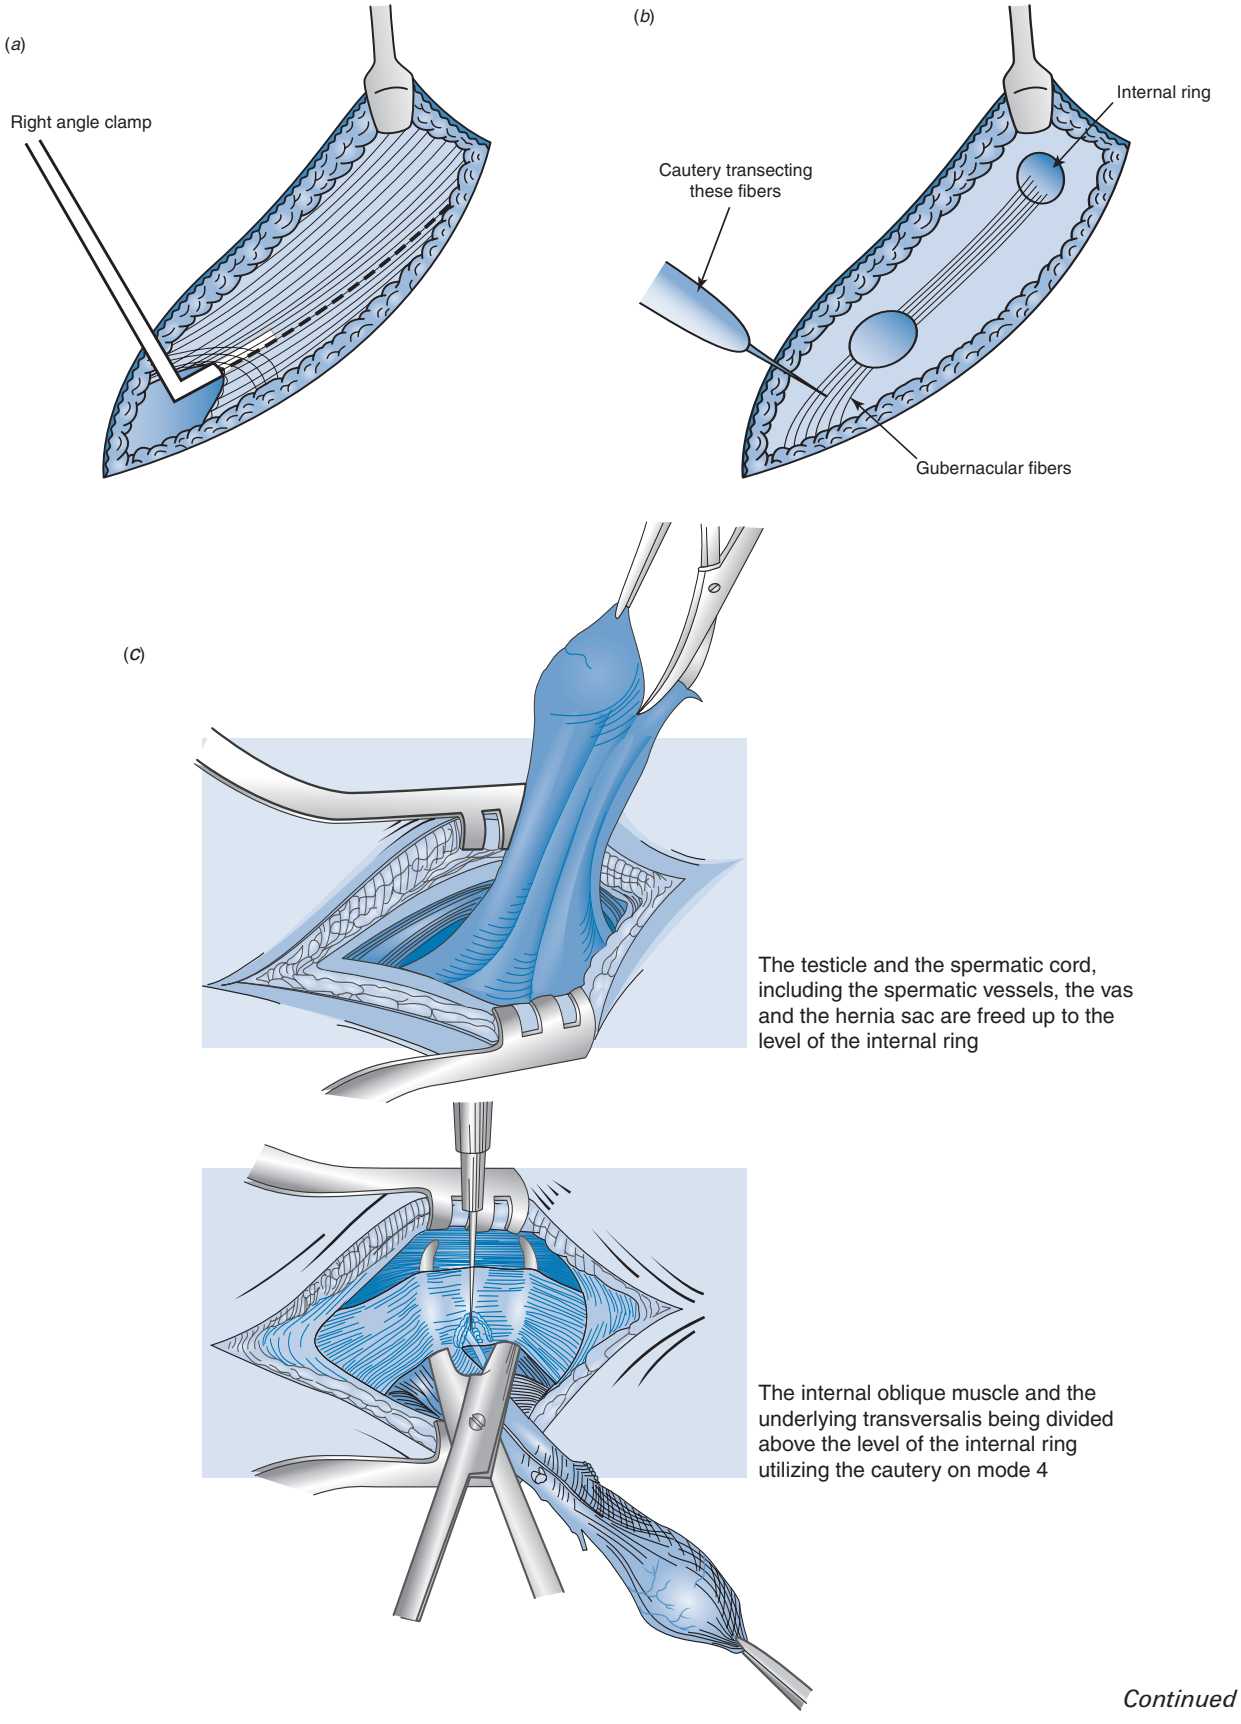
In experienced hands, laparoscopy is capable of providing nearly 100% accuracy in the diagnosis of the intra-abdominal testis with minimal morbidity; 22–58% of patients do not have a viable testis at the time of open or laparoscopic exploration.[34–42] In 2003, Barqawi et al[43] found that in 18 of 27 patients in whom an incomplete open exploration had been performed, an intra-abdominal testis or nubbin was found at the time of laparoscopy. In a similar study out of England, 59% (13 of 22) of testes deemed absent by groin exploration were identified on laparoscopy, and 12 of 13 were intra-abdominal.[44] Perovic and Janic[45] found 6 testes in 12 patients previously explored via an inguinal incision. Boddy et al[39] report 10 of 13 identified in previously reported negative explorations. Certainly, inguinal exploration in experienced hands is not expected to produce these results, but it is apparent that open exploration for the non-palpable testis is not straightforward. Suggesting inexperience as a factor, some of these testes and nubbins were intracanalicular or scrotal and missed at the

time of groin exploration. Kanemoto et al[46] found small nubbins missed at the time of groin exploration and detected at laparoscopy. Some clinicians suggest that if the ring is closed and atretic vessels and vas are seen entering the ring, then groin exploration is not necessary.[47] Zaccara et al[48] found that in 219 cases of non-palpable testis, there were 84 in which the ring was closed and the vessels were noted to be entering the ring (Figure 75.1g,h): in 21 of these where the vessels were large, 3 had a normal testis. In cases where the vessels were small and there was hypertrophy of the contralateral testis, they did not explore. In the ones that did not have hypertrophy, 1 of 30 had a viable testis in the canal.

Diagnostic inguinal exploration

A thorough dissection to the internal ring should be carried out during inguinal exploration. If a hernia sac is encountered, tugging on the back wall can often draw the testis out of its abdominal position. If the testis is still not evident, a limited local exploration of the retroperitoneum should be performed by incising the internal ring and mobilizing the peritoneum. The vas may be identified on the posterior peritoneum and can be traced to its juncture with the spermatic vessels. If this exploration is unsuccessful, then the peritoneum should be entered. The vas can be found on the back wall of the bladder. This can be traced distally to the spermatic vessels. Within the canal, if it appears that there are blind-ending vessels, they should be followed to the point of divergence from the vas above the internal ring. Occasionally, the vasal vessels can be prominent enough to be mistaken for the spermatic vessels, thereby leading to the diagnosis of vanishing testis when there is really a looping vas and an intra-abdominal testis. The identification of spermatic vessels coursing up the retroperitoneum diverging from the vas signals the end of the search. Blind-ending vessels is the sine qua none of testicular absence.[1]

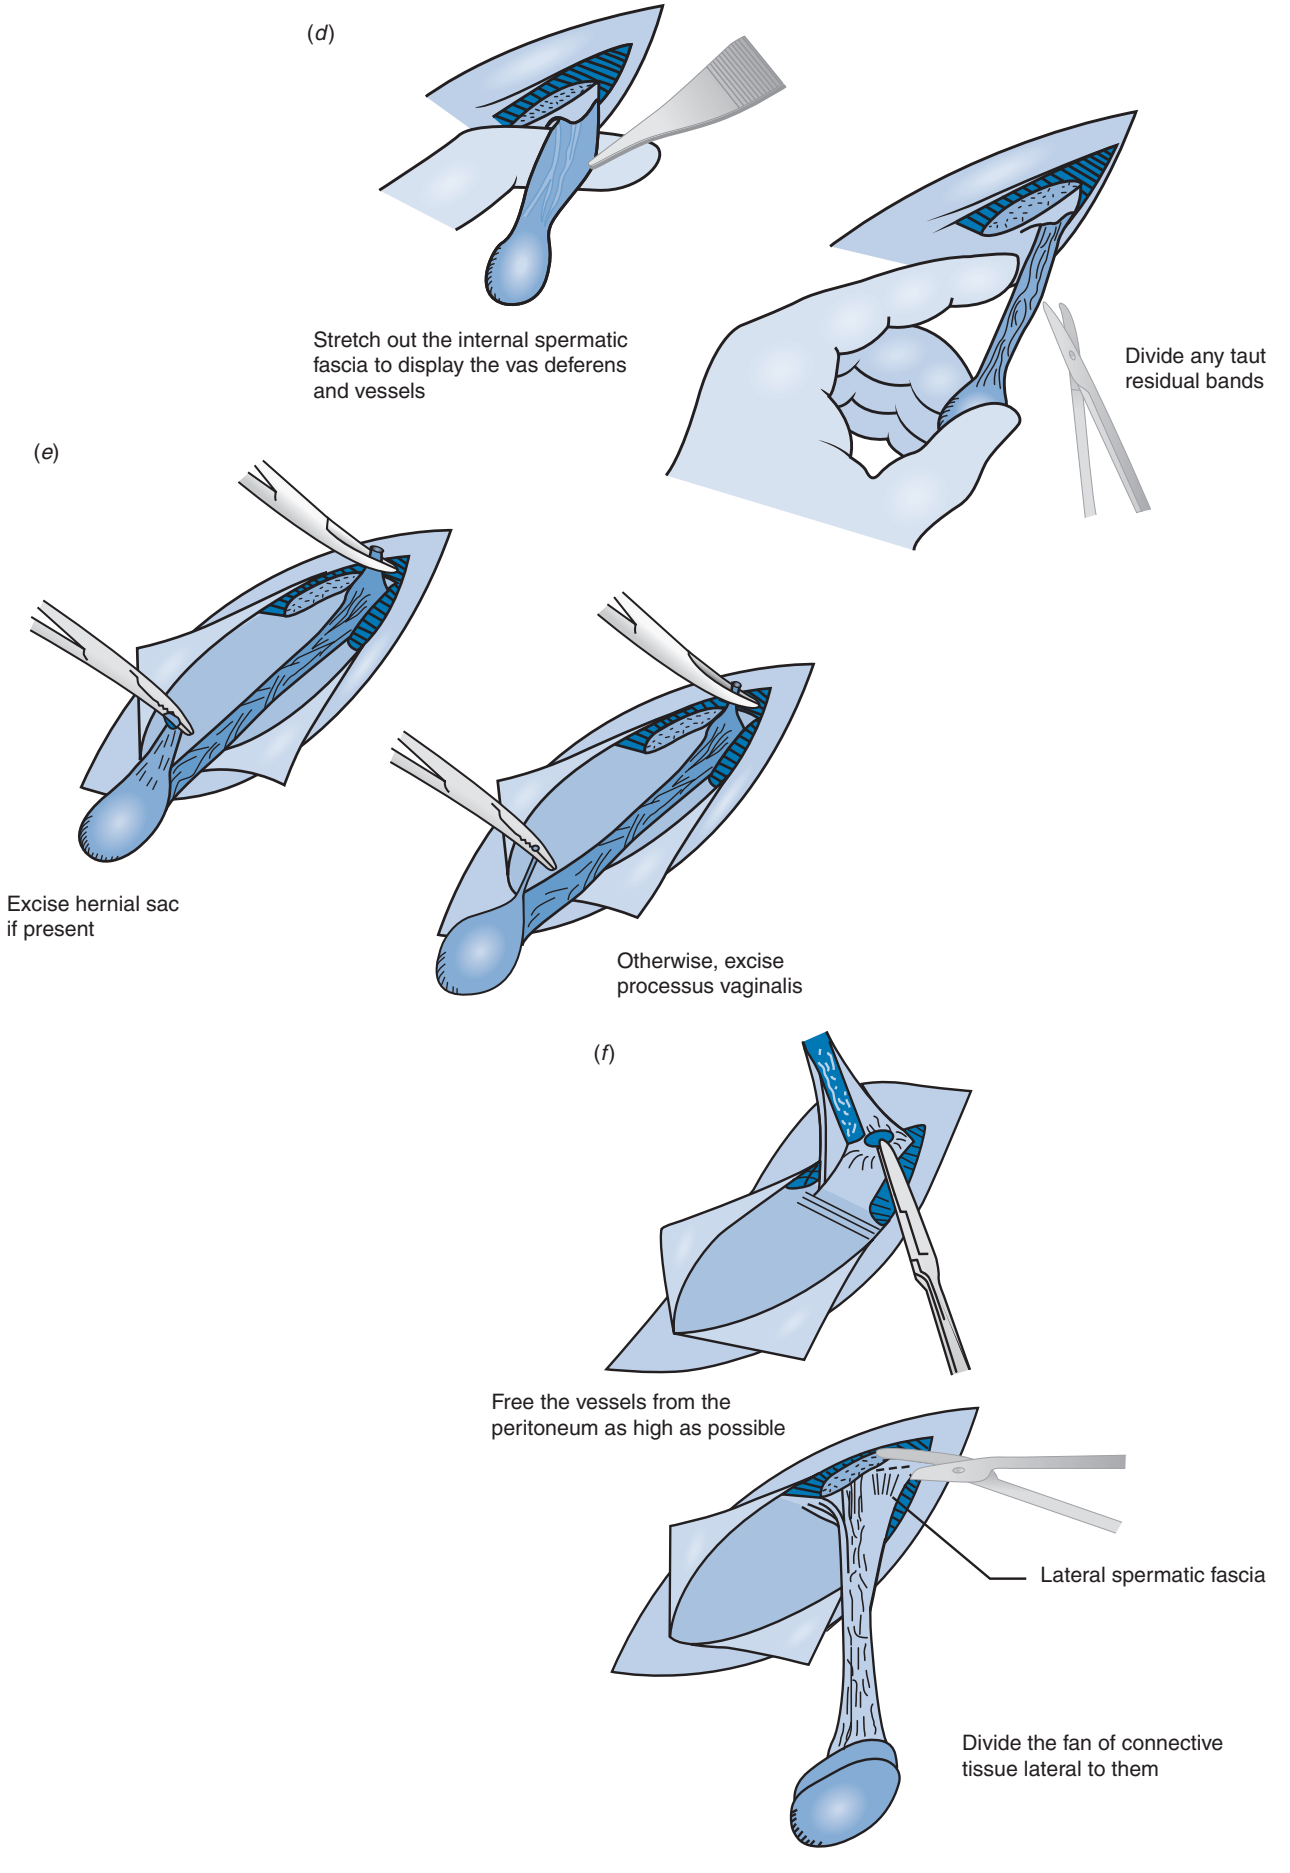
Diagnostic laparoscopy vs inguinal exploration



Cisek et al[49] suggested in their series of 263 non-palpable testis that the typical groin incision might have left the surgeon compromised in 66% of the cases compared with an approach optimized after laparoscopic testicular localization. Contrary to these findings, O'Hali et al[50] conclude that groin exploration is the ideal means for exploring for the non-palpable testis. Their conclusion that the presence of a hernia sac was associated with a testis in all cases and should lead to abdominal exploration was enough to obviate laparoscopy. Unfortunately, there were 14 of 19 cases of intra-abdominal testis when no hernia sac was noted. In our series, we have encountered many high testes with closed rings.[50] Thus, the presence of a hernia sac is associated with an undescended testis in all cases (155 non-palpable testes), but absence of a hernia sac does not mean absence of an intra-abdominal testis.

It is the author's bias that laparoscopy is a more intuitive and accurate method of surgical diagnosis for the non-palpable testis, but the controversy persists. In the end, a thorough understanding of the anatomy of the non-palpable testis as well as the persistence to identify the testicular vessels will determine success.

Techniques of orchidopexy



Standard inguinal approach to the undescended testis

The incision for a routine orchidopexy is performed in the skin crease just lateral and cephalad to the pubic tubercle. The incision is carried down to the external oblique fascia with care, since the testis is commonly found in the superficial inguinal pouch. If so, the testis is freed of the gubernacular attachments and the external oblique fascia is incised in the direction of the fibers (Figure 75.2a,b). If the testis is proximal to the external ring, it will be found after opening the external oblique fascia. The ilioinguinal nerve should be identified and preserved. The cord is dissected from the floor of the canal (Figure 75.2c). The internal spermatic fascia is then opened to separate the cord structures within this layer (Figure 75.2d). The hernia sac is found on the medial and anterior surface of the cord (Figure 75.2e). The more distal the dissection, the larger the sac tends to be, thereby making isolation of the sac more difficult. The hernia sac can be opened and carefully dissected off the vessels and vas, utilizing a fine scissor, or the edges of the sac can be grasped with a mosquito clamp and the sac rolled off the cord. Complete dissection of the hernia sac is essential to prevent hernia recurrences, as well as to obtain length on the cord. If additional length is needed, the lateral fascial attachments can be taken down into the internal ring (Figure 75.2f). It is transection of these attachments that allows the high testis to reach the scrotum. In some instances a vessel traveling to the hernia sac is present and this will act as an impediment to the placement of the testis in the

scrotum. This vessel can be transected without repercussions. If necessary, the internal oblique muscle can be incised for 1–2 cm and dissection of the lateral investing fascia can be carried further into the retroperitoneum (Figure 75.2c).

If after completing the dissection of the cord the testis still does not reach the scrotum, the floor of the canal can be incised and the testis brought on the lateral side of the epigastric vessels, or the epigastric vessels can be divided (Prentis maneuver) (Figure 75.2g). Some feel that this maneuver may add 5–10 mm of additional length to the cord. Care should be taken during the division of the floor of the canal, especially if the bladder is distended, as it is possible to inadvertently injure the bladder.

Once adequate length has been achieved, fixation of the testis in the scrotum is accomplished within a subdartos pouch (Figure 75.2h). Avoid a pouch that is laterally placed, as this will yield an unsatisfactory result. A natural tendency but one which is incorrect is to follow the path of the ectopically located testis and use this to enter the scrotum to create the subdartos pouch. Instead, creating the neocanal along the base of the penis will avoid the tendency to drift laterally and result in a poorly placed testis. With a finger in the scrotum, the location for the pouch is selected and an incision is made. The pouch is created using a tenotomy scissor, with the larger portion of the dissection directed inferiorly. The pouch should be generous in size so that the testis can fit without excessive tension. A clamp is passed on the fingertip into the inguinal region and a portion of the cauda gubernaculum or a fixation stitch is pulled into the scrotum (Figure 75.2i). The testis is fixed in the scrotum using absorbable stay sutures at three points or, if a fixation stitch is used, this suture is loaded on a free Keith needle and brought out the inferior wall of the scrotum (Figure 75.2j). The scrotum is closed and the fixation stitch is tied loosely at the skin level, either to itself or over a pledget, depending on the amount of tension.

The staged orchidopexy

In cases where inguinal exploration is performed and where it is not feasible to perform a vessel ligation to bring the testis down in either one or two stages, the

staged orchidopexy may be necessary. The testis can be fixed to the pubic tubercle to prevent it from pulling up higher into the groin. Historically, silastic sheeting was used to wrap the cord to facilitate subsequent dissection. The second-stage procedure is carried out 6 months to 1 year later in the hopes of achieving greater length on the cord. With modern techniques of orchidopexy, the staged procedure is rarely necessary.

Orchidopexy by spermatic vessel transection

Orchidopexy by spermatic vessel transection was first described by Bevin in 1903.[31] It was not popularized until Fowler and Stephens better characterized the blood supply of the testis in 1959.[51] The Fowler–Stephens analysis revealed that the testicular artery receives constant collateral communication from the vasal and cremasteric arteries before it reaches the testis. They believed that transection of the main artery too close to the testis would cut off collateral blood supply and lead to atrophy. They advocated temporarily occluding the internal spermatic vessels to test the capacity of the testicle's collateral blood supply, as well as high ligation of the vessels above the collaterals. Johnston[52] advocated leaving a medial broad strip of peritoneum along with the vas to further preserve collateral blood supply (Figure 75.3). Success rates as high as 89% have been reported utilizing their technique.[53]

Recent studies of the vascular anatomy by Jarow[54] indicate that large-caliber anastomotic channels exist between the testicular and vasal arteries. These channels typically run beneath the tunica albuginea and communicate with the inferior pole of the testes. Koff feels that high ligation may in fact contribute to testicular ischemia by limiting dissection between the ascending and descending vasal loops to unfold the testis. He also proposes that additional collateral blood flow can be derived from the distal spermatic vessels that are left intact. Koff modified the Fowler–Stephens procedure by[55] dividing the vessels as close to the testis as possible (Figure 75.4). He achieved a success rate of 93% in a series of 39 low-spermatic transactions, excluding those with prior inguinal surgery. From our own series of laparoscopic Fowler–Stephens orchidopexies[56] we have had an overall success rate of 85%, but when patients who also had prior inguinal surgery or manipulations of the cord are eliminated the success rate is 96%. The principles of both high and low ligation are similar in that avoidance of manipulation of the vas and cord should be of the highest priority to prevent damaging the delicate blood supply. Preservation of the peritoneum between the vessels and vas is essential to the success of the procedure.

Wang and Shaul[57] have emphasized preservation of the gubernacula in Fowler–Stephens procedures, and have had success rates comparable with those reported by Chang et al[58] and Samadi et al[59] when virgin cases only were included.

Jones incision for the non-palpable testis

When the testis is non-palpable on examination in the office and is subsequently found to be a high canalicular or peeping testis at the time of surgery, the Jones approach[60] is potentially useful. The technique was combined with diagnostic laparoscopy by Gheiler et al,[61] with 18 out of 19 testes achieving satisfactory

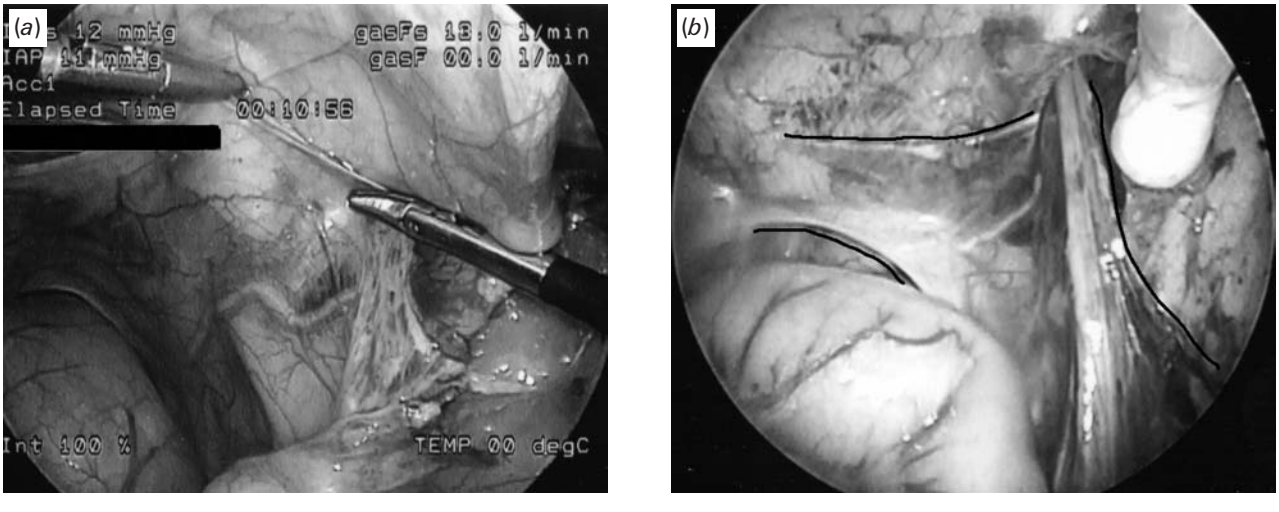

Figure 75.3 (*a*) Peritoneal tongue in a Fowler–Stephens orchidopexy. (*b*) Peritoneal triangle with vas in the center.

scrotal positioning. The one failure was in a patient who underwent simultaneous Fowler–Stephens orchidopexy. The technique involves making an incision medial to the anterior superior iliac spine (ASIS) (Figure 75.5a). The muscle is split and the retroperitoneum is entered (Figure 75.5b). The peritoneum is mobilized medially and the internal inguinal ring is identified (Figure 75.5c). The sac is identified and opened and the testis is brought into the field (Figure 75.5d). The hernia sac is ligated and the spermatic vessels are mobilized by incising the lateral spermatic fascia superiorly (Figure 75.5e). The subcutaneous tissue is mobilized off the external oblique fascia to the level of the pubic tubercle (Figure 75.5f). An opening large enough to allow the testis to pass through the abdominal wall at the pubic tubercle is made and the testis is delivered (Figure 75.5h). The testis is then fixed in the scrotum in a subdartos pouch.

Microvascular autotransplantation of the testis

With the advent of microvascular surgery in the 1970s the first reported cases of microvascular autotransplantation of the testis were reported by Silber and Kelly[62] in 1976. A large series of 27 autotransplantations reported a success rate of 96%.[63] Docimo[64] reported a combined success rate in the literature of 83.7% in a total of 86 cases reported up to 1995 (Table 75.3). The procedure, as described by Bukowski et al,[63] is as follows: a high inguinal incision is used to avoid injuring the inferior epigastric vessels. The dissection is then carried down to the level of the inferior epigastric vessels. The retroperitoneum is entered and the colon is mobilized. The testicle is identified and the testicular vessels are isolated and divided as proximally as possible. The testis is mobilized in a fashion similar to the Fowler–Stephens mobilization, maintaining a wide strip of peritoneum which is taken with the vas deferens. The testis is brought through an anterior abdominal incision and placed in the scrotum in a subdartos pouch. Care is taken to make sure that there is no tension on the vas deferens, which can be mobilized back to the bladder if needed. The inferior epigastric vessels are isolated. Small branches are ligated until 8–9 cm has been freed beneath the rectus muscle towards the umbilicus. The inferior epigastric vessels are ligated distally and clips are placed proximally. The proximal vessels are opened and flushed with heparinized saline. The testicular artery is then anastomosed to the inferior

Data from Docimo[64]

epigastric artery. The testicular artery typically measures 0.5–1 mm in diameter, whereas the epigastric artery is 1–1.5 mm in diameter. The veins are usually similar in size, measuring 1 mm in diameter. An end-to-end or end-to-side anastomosis is used. Patients are typically kept immobilized for 24 hours. Tackett et al[65] reported on 17 cases of microvascular anastomosis and laparoscopic testicular mobilization, thereby minimizing the intra-abdominal dissection. The overall success rate was 88% (15/17). Although the success rates with this procedure are quite impressive, they are probably not better than the success rates obtained by meticulous vessel transections solely. In our series and those of Kogan[53] and Koff[55] similar results were obtained without utilizing the microvascular anastomosis. The indications for microvascular autotransplantation are therefore unclear.

Therapeutic laparoscopy for the undescended testis

Laparoscopic vessel ligation

Bloom[66] was the first to combine diagnostic laparoscopy and operative intervention when he fulgurated the vessels of intra-abdominal testes and performed a second-stage open Fowler–Stephens orchidopexy at a later date.

Laparoscopic orchidopexy

Laparoscopic orchidopexy seemed to be the logical extension to early attempts at vessel ligation by Bloom[66] and routine diagnostic laparoscopy. The procedure allows the surgeon to transition from a diagnostic mode to an operative procedure. Laparoscopic orchidopexy was first described by Jordan et al in 1992.[67] Subsequently, there have been numerous reports describing this technique.[68–72] Our original series was the largest series of laparoscopic orchidopexies, and now consists of 203 procedures.[72] Our success rate in getting the testis in a scrotal position without atrophy is 95% in the cases not involving vessel transections.[59]

The original description by Jordan et al[67] remains relatively unchanged, except for some minor variations in how to bring the testis out of the abdomen. Routine laparoscopy is performed via an infra- or supraumbilical incision. Open trocar placement is preferred in our series (Figure 75.6). The bladder should be emptied by catheterization and the catheter should remain throughout the procedure to prevent injury to the bladder. This is especially critical at the time that the neoring is created. In the prune belly patient, extra caution is necessary when placing the initial trocar, since the urachal diverticulum may extend all the way to the umbilicus. In these cases a supraumbilical incision should be used.

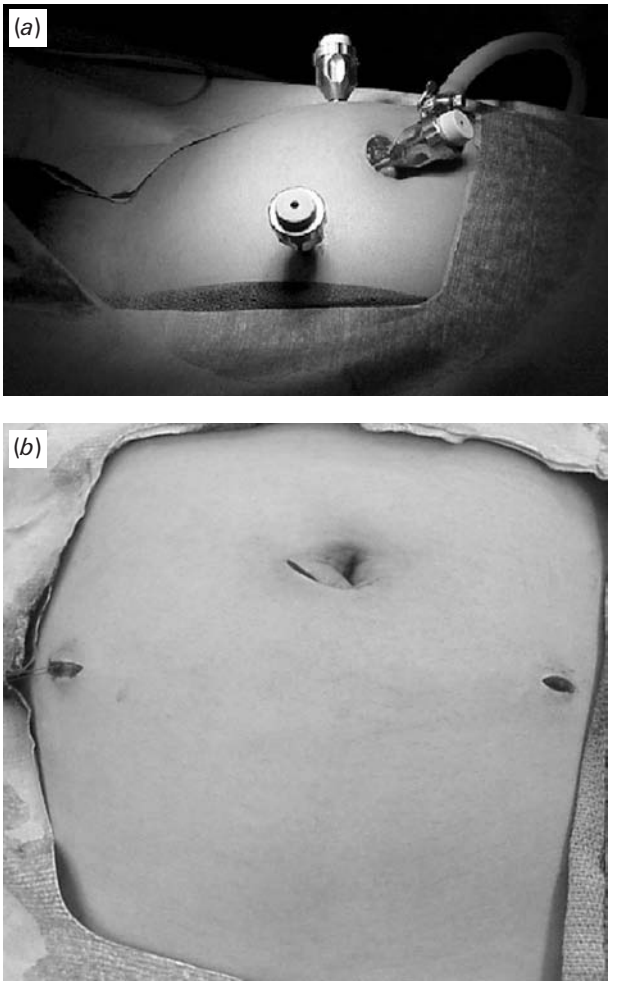

Figure 75.6 (*a* and *b*) Trocar placement.

Once in the abdomen, inspection of the internal ring should be performed. The vas and vessels should be seen approaching the ring. The vessels are generally thinner and the vas will tend to have prominent vessels traveling with it in cases of atrophy (see Figure 75.1). A closed ring does not always signify an absent testis. Very high abdominal testes may not have any attachments to the internal ring and may be situated behind the bowel (Figure 75.7). If no vessels or vas are seen approaching the ring, additional trocars should be inserted to reflect the colon. The contralateral side can be used as reference in cases of unilateral undescended testis. The testis will be found within 1 cm of the ring in the majority of cases. Peeping

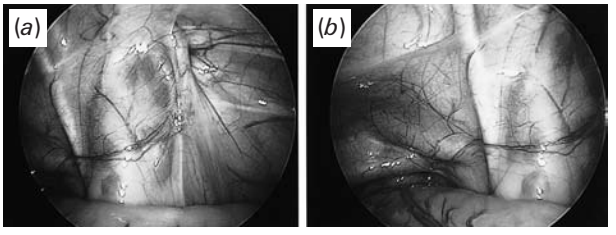

Figure 75.7 (*a, b*) Closed internal rings with absence of vas. In both the testis was out of sight. (*c*) Note the absent vas in the peritoneal triangle. (*d*) Note the testis with absence of epididymal structures.

testes can be pushed into the abdomen by pressing on the canal (Figure 75.8).

Once the decision to perform a laparoscopic orchidopexy has been made, the working trocars are placed under direct vision. The size of the working trocars depends on the need for vascular clips. The smallest clip applicator currently available is 5 mm. Trocars are placed at the level of the umbilicus and along the mid clavicular line. Inspection of the placement site will help avoid injury to the epigastric vessels. In very young children placement of the trocars above the level of the umbilicus is helpful to avoid crossing instruments. Once the trocars are in place, two grasping forceps can be used to pull on the gubernaculum and bring as much of it into the abdomen as possible (Figure 75.9). Sometimes, the vas is looping into the gubernacular tissue, and can be injured during this maneuver or gubernacular division. The gubernaculum is transected using an electrified scissor with a minimal amount of cautery to prevent dissipation of heat to the vas. The dissection is carried medially over the bladder, incising the peritoneum distal to the vas and moving towards the contralateral median umbilical ligament. A generous segment of peritoneum should be maintained between the cut edge and the vas. The dissection is then carried lateral to the spermatic vessels to the colon (Figure 75.10). The peritoneum is then incised medially over the proximal spermatic vessels. This is critical in providing additional length for proper mobilization of the testis into

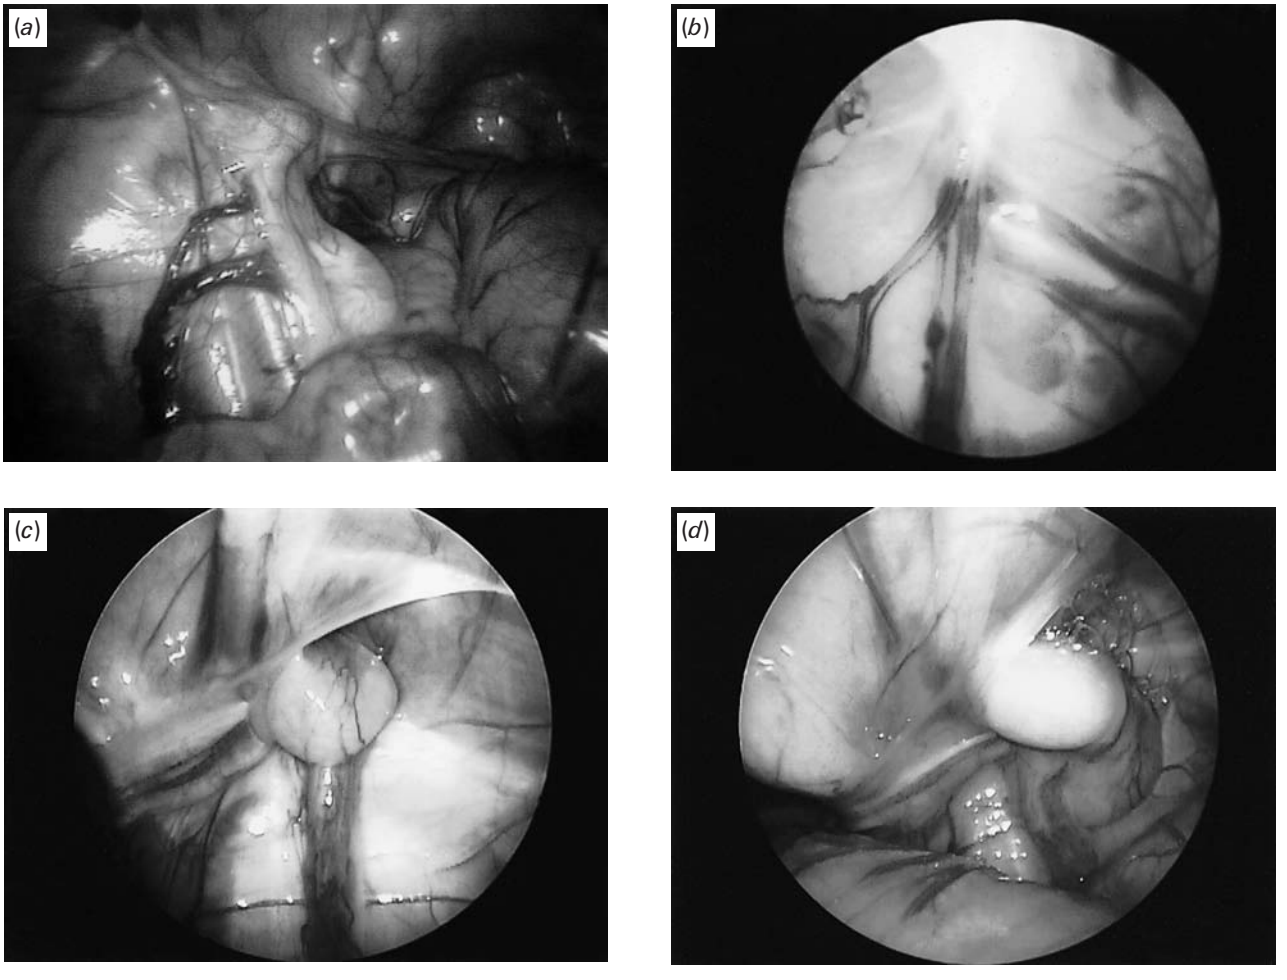

Figure 75.8 (*a*) Intra-abdominal testis. (*b*) Normal contralateral internal ring. (*c* and *d*) Peeping testis.

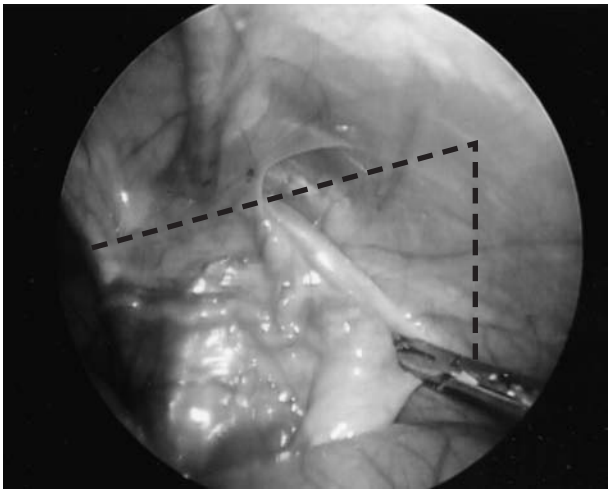

Figure 75.9 Gubernacular fibers. Dashed lines are incision lines of the peritoneum.

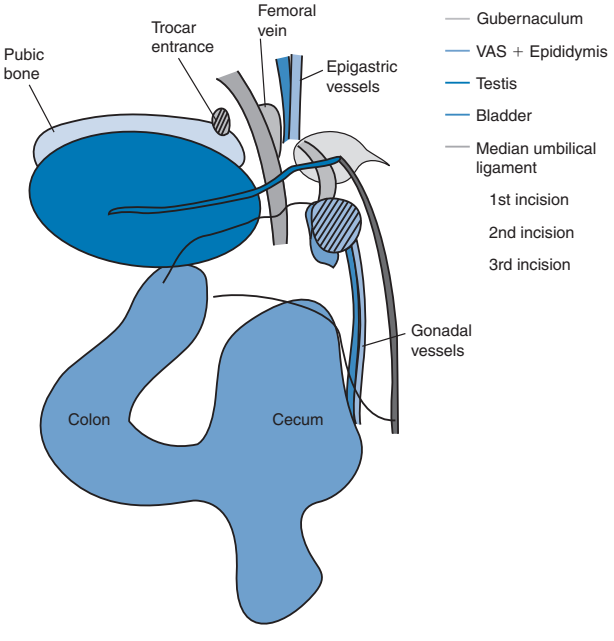

Figure 75.10 Representive view of the pelvis with incision lines.

the scrotum (Figure 75.11). This also leaves a generous triangle of peritoneum between the vessels and vas in case vessel transection is necessary.

Laparoscopic Fowler–Stephens orchidopexy as performed in our series consists of the high ligation technique. A large wide wedge-shaped strip of peritoneum has been preserved (see Figure 75.3). We have encountered only two failed Fowler–Stephens orchidopexies to date using the laparoscopic one-stage Fowler–Stephens orchidopexy in a virgin case.

The testis is brought out of the abdomen via a neoinguinal canal created in the anterior abdominal

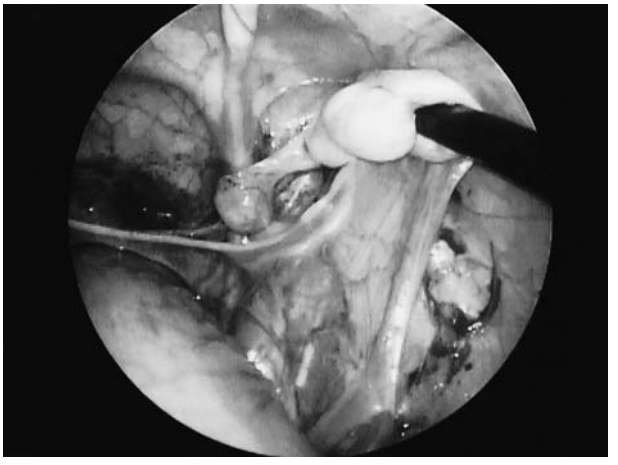

Figure 75.11 Testis freed up after incising over the bladder and lateral pelvic wall.

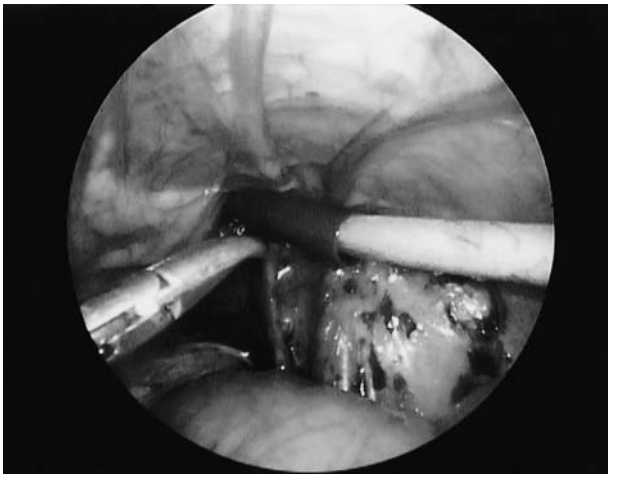

Figure 75.12 Neoinguinal ring between bladder and medium umbilical ligament.

wall near the pubic tubercle (Figure 75.12). We prefer to bring the testis out medial to the median umbilical ligament and lateral to the bladder. This is done by dissecting in the space between the aforementioned structures and getting down to the pubis. The scrotum is invaginated by the index finger, and the endodissector is placed over the pubic bone and the external inguinal ring is palpated with the dissector and the finger invaginating the scrotum. Once the ring is identified, the dissector is driven into the scrotum guided by the index finger (Figure 75.13). A small scrotal incision is made and the dissector is brought out into the field. A subdartos pouch is created and a 5 mm trocar is placed over the dissector and guided into the abdomen (Figure 75.14). This trocar can be used to apply clips if a vessel transection

Figure 75.13 A subdartos pouch has been created.

Figure 75.14 A 5 mm trocar back-loaded over the instrument.

is necessary while using microinstrumentation. The gubernacular attachments of the testis are grasped with an endoallis clamp and the testis is delivered into the field. The testis is fixed in the scrotum in the usual fashion.

If testicular positioning is inadequate, further dissection can be done while holding the testis in the scrotum. If the length is inadequate, vessel transection can be done at this point with a clip applier. Since the vas and its vessels have never been touched, this allows a successful Fowler–Stephens orchidopexy. Concerns regarding the possible development of hernias at the internal ring and along the inguinal canal have been largely unfounded; thus we do not attempt to close the ring. There is one reported hernia after laparoscopic orchidopexy,[73] but this seems to be a rare exception.

Risks and complications

Risks of orchidopexy include bleeding, infection, testicular atrophy, testicular malposition, and recurrence of inguinal hernia. Complications associated with laparoscopic orchidopexy are the same, with the addition of possible injuries from cautery or trocar placement. Injury to the iliac vessels during dissection is possible during open or laparoscopic orchidopexy. Avulsion of the gonadal vessels or inadvertent Fowler–Stephens orchidopexy is another complication, more commonly reported with the laparoscopic approach. This usually occurs during delivery of the testis into the scrotum. This can also occur when the surgeon pulls vigorously on the testis during dissection. We have encountered this complication without the loss of the testis. The proximal vessels may retract and go into spasm, making identification difficult. These vessels need to be found and clipped. The vessels from the testis can generally be pulled into the scrotum and ligated. Another potential catastrophic complication is injury to the femoral vessels. This can be avoided by making sure that the endodissector is passed from the ipsilateral port and aimed medially at all times during development of the neocanal. Also dissecting down to the pubic bone in the window between the bladder and the medial umbilical ligament will prevent injuries to the femoral vessels as well as injuries to the bladder. Bladder injuries may occur when the bladder is not decompressed throughout the procedure. Obstruction of the ureter due to tension on the vas has been reported rarely, and has been associated with the Fowler–Stephens procedure.

Much controversy exists in the literature and has been publicly expressed about the risks of adhesions postlaparoscopy. We have not encountered adhesions in our patients that have had multiple laparoscopic procedures nor have we encountered any episodes of bowel obstruction postlaparoscopy secondary to adhesions. Bowel obstruction is a potential complication of laparoscopy in the immediate postoperative period. This is due to herniation of bowel into a trocar site that was inadequately closed. Closure of all trocars sites 5 mm or greater is recommended for children. The advent of microendoscopic equipment and non-cutting trocar technology reduces the risk of herniation and bowel obstruction.

Outcomes of orchidopexy

Conventional orchidopexy for the peeping testis has a satisfactory scrotal placement rate of 82% and for the

intra-abdominal testis a rate of 74%.[64] Hazebroek et al[38] had an atrophy rate of 16% for open orchidopexies for peeping or intra-abdominal testis on long-term follow-up. They had a 33% atrophy rate for their vessel transection orchidopexies that included one-stage, two-stage, and revascularization procedures. Laparoscopic orchidopexy achieved a 97% combined satisfactory scrotal placement in our series[59] of patients and there were similar results in other large series. Results with Fowler–Stephens orchidopexy are also superior to those reported in the cumulative literature. The staged Fowler–Stephens procedure was thought to be a better alternative to one-stage vessel transection, allowing collateral blood supply to mature and support transplantation of the testis more readily. This concept was supported by work done by Pascual et al[74] in rats utilizing a xenon washout technique to measure blood flow at 1 hour and 30 days after ligation. Results demonstrated an 80% reduction in blood flow at 1 hour after ligation. However, 30 days later, blood flow returned to normal pretreatment values. Some authors have reported very high success rate with this technique.[68,75] However a review of the literature by Docimo[64] in 1995 revealed no significant difference statistically between one-stage and two-stage vessel transactions prior to the era of laparoscopic orchidopexy. He found that staged Fowler–Stephens orchidopexy had an overall success rate of 76.8% (43/56 testis). When compared with one-stage Fowler–Stephens orchidopexy during the same time period (post 1985), the success rate was 68.5% (76 of 111). These results again tend to prove that meticulous preservation of the vasal blood supply is the most important factor in cases of spermatic vessel transection. Despite this, the majority of laparoscopic practitioners still adhere to the superiority of the staged procedure.

The expense of laparoscopic procedures has been a concern in the past. Lorenzo et al[76] reported on a computer-based analysis of costs for surgery for non-palpable testis and found that there was no difference between open and laparoscopic approaches. The costs of laparoscopy continue to decrease as reusable instruments improve and operative times decrease with experience.

Testicular tumors

76

Jonathan H Ross

Introduction

Prepubertal testicular tumors are less common than other pediatric urologic tumors such as neuroblastoma and Wilms' tumor, and testicular tumors are far more common in adults than in children. Historically, the management of pediatric testicular tumors has been based on experience in adults. Indeed, testicular tumors in adults and children have many similarities. Both usually present with a testicular mass and are treated initially with excision of the primary tumor. In both children and adults, testicular tumors are particularly sensitive to platinum-based chemotherapy, which has revolutionized the management of testicular cancer throughout the age spectrum.[1,2] However, there are important differences between testis tumors occurring in children and adults. These differences occur in the tumor histopathology, malignant potential, and pattern of metastatic spread. The patients themselves are also dissimilar, with different concerns regarding surgical morbidity and preservation of testicular function. The introduction of a Prepubertal Testicular Tumor Registry by the Section on Urology of the American Academy of Pediatrics (AAP) in 1980 allowed for the accrual of valuable epidemiologic information.[3] Recent multicenter and prospective clinical trials have further advanced our understanding of these tumors and their management.[4–6]

Epidemiology

There is a bimodal age distribution for testis tumors, with one peak occurring in the first 2 years of life, and a second larger peak occurring in young adulthood. The incidence of pediatric testis tumors is 0.5–2.0 per 100 000 children, accounting for 1–2% of all pediatric tumors.[7] Testis tumors are categorized, based on the presumed cell of origin, into stromal tumors and germ cell tumors. In the Prepubertal Testicular Tumor Registry of the Section on Urology of the AAP, the majority of primary testis tumors were yolk sac tumors followed by teratomas and stromal tumors.[3] However, selection bias can lead to an overrepresentation of malignant tumors in registries. Indeed several recent studies have found teratoma to be more common than yolk sac tumor.[8–12] Table 76.1 summarizes the distribution of testis tumors in the Prepubertal Testicular Tumor Registry and a multicenter review of prepubertal testicular tumor pathology specimens. Because teratomas and most stromal tumors are benign in children, the percentage of prepubertal testis tumors that have malignant potential is much lower than the 90% of tumors in adults.

Evaluation

The majority of patients with a testicular tumor will present with a testicular mass noted by the patient, a parent, or a healthcare provider. These masses are usually hard and painless. Occasionally, patients may present with a hydrocele or pain due to torsion or bleeding into the tumor. Physical examination can usually distinguish testicular tumors from other scrotal masses such as hydroceles, hernias, or epididymal cysts. When the physical examination is equivocal, an ultrasound of the testicles can resolve the issue. Ultrasound can also assist in characterizing the lesion. Although ultrasound cannot reliably distinguish malignant from benign testicular tumors, cystic tumors are more likely to be benign in children.

Tumor markers typically utilized in the evaluation and management of adult testis tumors include human

Table 76.1 Distribution of tumor types in the 395 primary testis tumors registered in the Prepubertal Testicular Tumor Registry of the Section on Urology of the American Academy of Pediatrics[3] and 98 tumors in a multicenter consecutive series of patients[12]

Tumor type	Percent of tumors in Registry	Percent of tumors in multicenter study
Germ cell:		
Yolk sac	62	15
Teratoma and epidermoid cyst	26	62
Stromal:		
Leydig cell	1	4
Sertoli cell	3	3
Juvenile granulosa cell	3	5
Unspecified stromal	4	1
Gonadoblastoma	1	2

chorionic gonadotropin (hCG) and alpha-fetoprotein (AFP). Whereas hCG is elaborated in a significant number of mixed germ cell tumors, this tumor type is vanishingly rare in prepubertal patients. It is therefore not a helpful marker for this population. On the other hand, the AFP level is elevated in 90% of patients with yolk sac tumor and can be very helpful in the preoperative distinction between yolk sac and other tumors (almost all of which are benign). One caveat is that the AFP level is quite high in normal infants. The AFP levels are highly variable in infants; typical levels range from approximately 50 000 ng/ml in newborns, to 10 000 ng/ml by 2 weeks of age, 300 ng/ml by 2 months, and 12 ng/ml by 6 months of age.[13] Therefore, AFP levels among patients with yolk sac tumor and benign tumors overlap in the first 6 months of life, making it a less helpful indicator for distinguishing tumor types in young infants (Figure 76.1).[14]

Since many, if not most, prepubertal patients will have a benign tumor, the metastatic evaluation may be deferred until a histologic diagnosis of the primary tumor is obtained. A preoperative metastatic evaluation may be undertaken in patients over 6 months of age with an elevated AFP level, who probably harbor a yolk sac tumor. Metastases from yolk sac tumor typically occur in the lungs and the retroperitoneal lymph nodes. A chest X-ray or chest computed tomography (CT) scan and abdominal CT are obtained. Postoperative AFP levels are also followed. The half-life of AFP is approximately 5 days. Failure of an elevated AFP to decline as expected after removal of the primary tumor is evidence of persistent metastatic disease.

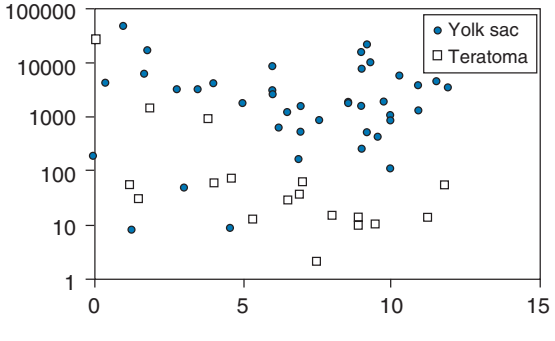

Figure 76.1 Alpha-fetoprotein (AFP) level (ng/ml) as function of age for infants with yolk sac tumor in the Prepubertal Testicular Tumor Registry of the Section on Urology of the American Academy of Pediatrics. (Reprinted from Ross et al,[3] with permission.)

Surgical management

The standard initial treatment for a malignant testicular tumor is an inguinal orchiectomy with early control of the vessels. In prepubertal patients, this approach should be applied only to patients >6 months of age with an elevated AFP.[3] In all other patients, a benign tumor is likely to be present, and the initial surgical management should be an excisional biopsy with frozen section analysis. The exploration is accomplished through an inguinal incision, with occlusion of the testicular vessels (Figure 76.2). Failure to follow these guidelines, particularly scrotal violations, may increase the recurrence rate if the tumor proves to be a yolk sac tumor.[15] If the frozen section reveals a likely malignancy, then the entire testis is removed. If a benign histology is confirmed (usually teratoma), the remaining testis is closed with chromic suture and returned to the scrotum. Even large tumors can be enucleated with preservation of significant testicular tissue (Figure 76.3).

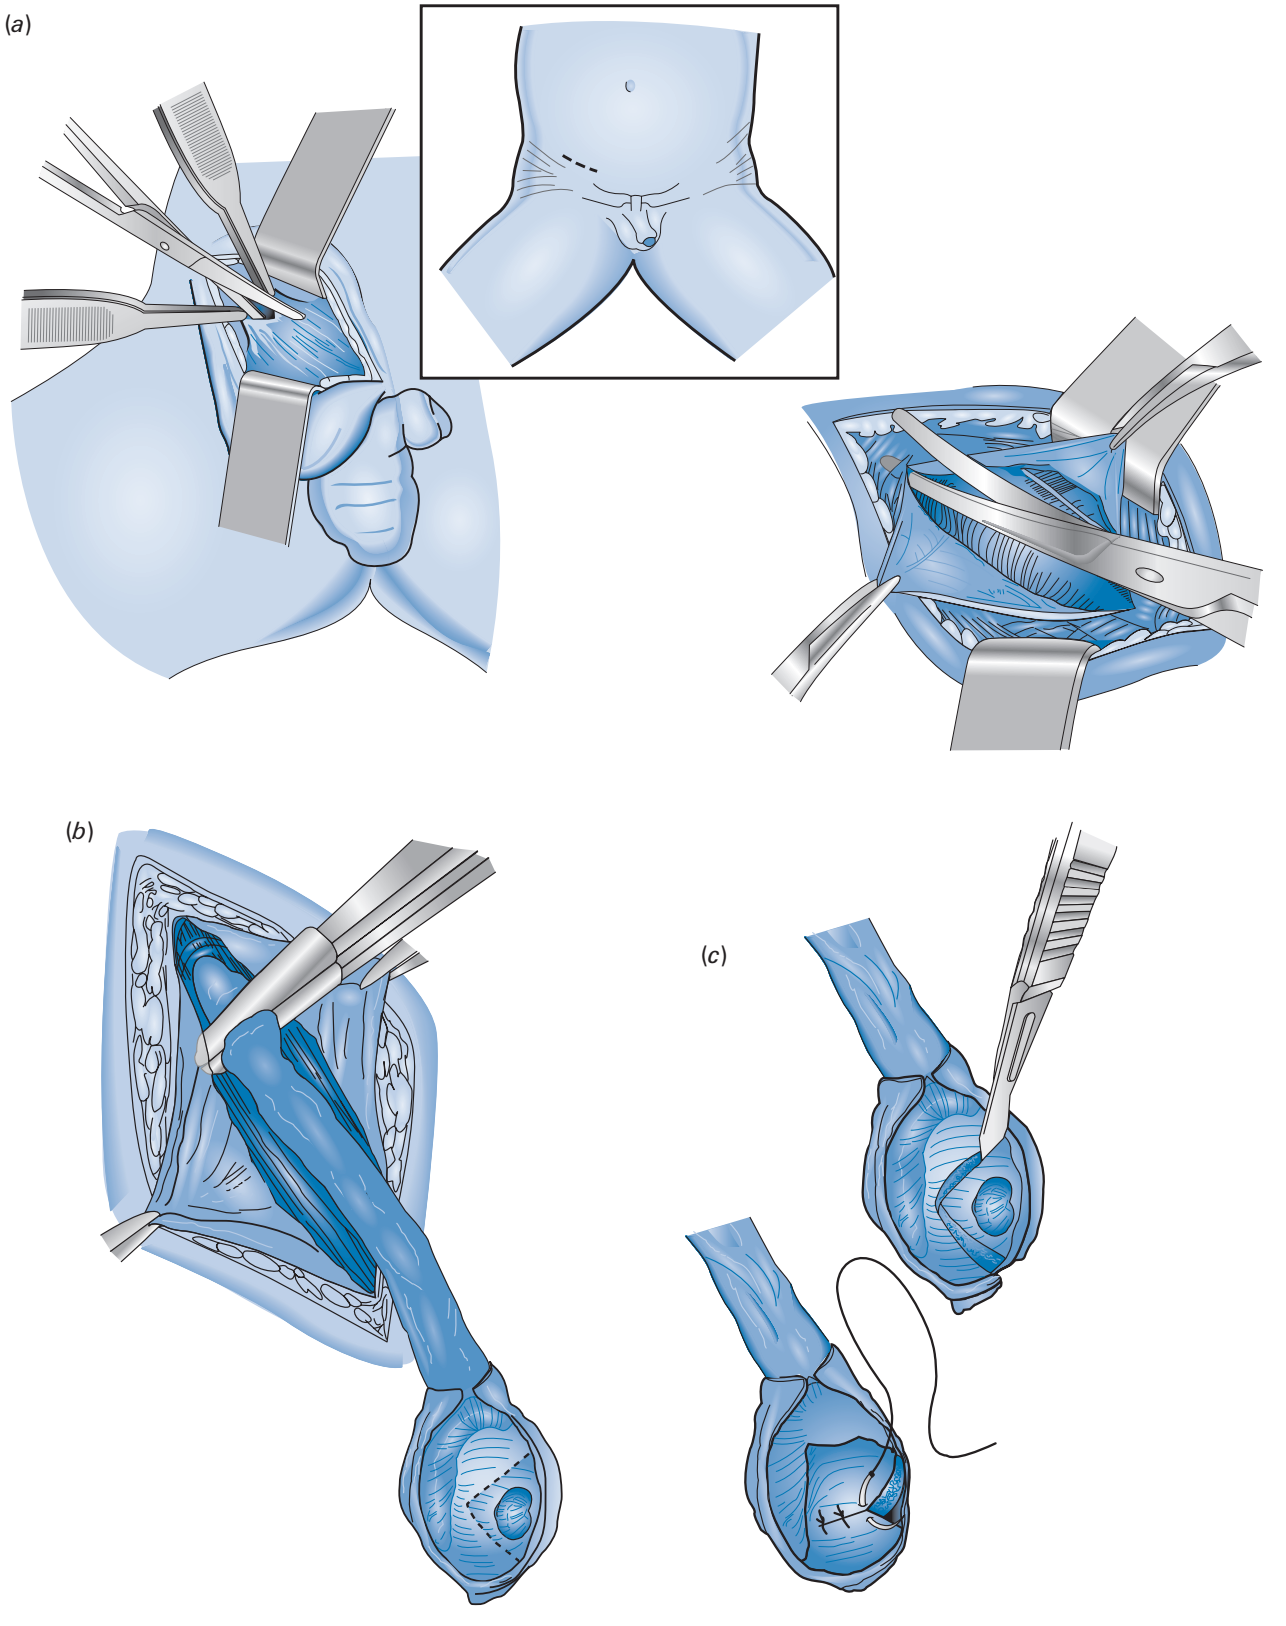

Figure 76.2 Inguinal exploration with testis-sparing tumor excision. (*a*) An inguinal incision is made and Scarpa's fascia is opened, exposing the external oblique aponeurosis. This is opened along the length of its fibers through the external ring, exposing the spermatic cord structures. (*b*) The vessels are temporarily occluded and the testis delivered into the operative field. The hydrocele sac is opened and the tumor sharply excised. If a benign tumor is confirmed on frozen section, then the remnant testis is closed and returned to the scrotum.

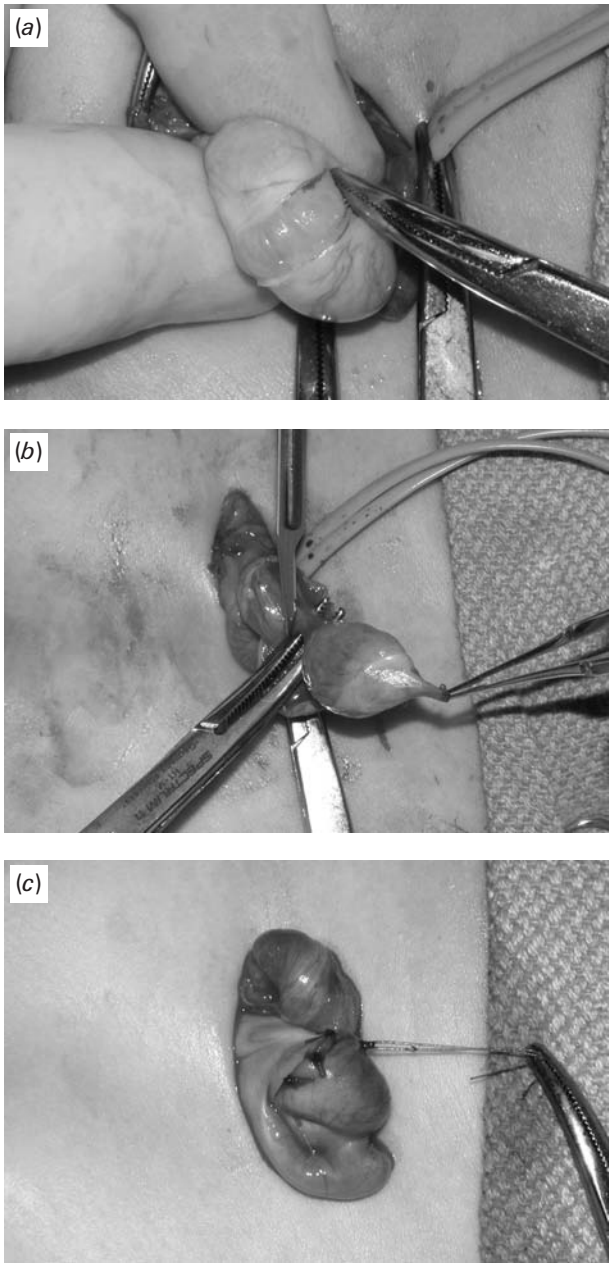

Figure 76.3 Enucleation of a benign tumor. (*a*) With the vessels occluded, an incision is made in the testicular tunic, exposing the cystic tumor. (*b*) The tumor is enucleated and detached from the testis. (*c*) The testis is closed with interrupted suture.

One concern with this approach is the malignant potential of the remnant testicular tissue. In adults, 88% of testicles with teratoma harbor carcinoma in situ (CIS) elsewhere in the testis, and so orchiectomy is still an appropriate management in postpubertal patients.[16] However, in studies of prepubertal teratoma, with the exception of one case, no such finding has been evident.[17–19] Rushton et al reviewed the histopathology of 17 testes removed for teratoma.[18] No multifocal tumor or CIS was found in any specimen. In initial small series of testis-sparing surgery for prepubertal benign tumors, there have been no cases of recurrent tumor in the preserved testicular remnant.[10,11,17,18,20] In 1999, Sugita et al reported on 27 patients with teratoma, 17 of whom were treated with partial orchiectomy.[11] With a mean follow-up of 10 years, there were no recurrences and no cases of testicular atrophy. In these studies, testes undergoing testis-sparing tumor excision appear to maintain normal testicular volume postoperatively.

Adjuvant therapy for malignant testicular tumors

Virtually all malignant germ cell tumors in children are yolk sac tumors. The typical mixed germ cell tumors seen in adults occur only after puberty. There is little data regarding the behavior of mixed germ cell tumors in adolescents, although they appear to exhibit behavior similar to that seen in adults.[21] It is therefore assumed that they should be managed as in adults with observation, retroperitoneal lymph node dissection (RPLND), and/or chemotherapy, depending on the specific histology and stage of the disease. This seems a reasonable approach until further studies in adolescents with testicular malignancies are undertaken.

Yolk sac tumor is a yellow to pale gray solid tumor. It has been referred to by a variety of other names, including endodermal sinus tumor, orchioblastoma, juvenile embryonal carcinoma, mesoblastoma vitellinum, clear cell adenocarcinoma, extraembryonal mesoblastoma, and archenteronoma.[7] A variety of histologic patterns may occur. Positive staining with AFP supports the diagnosis of yolk sac tumor. Classic glomeruloid (Schiller–Duval) bodies and embryoid bodies may be present. These structures are clusters of cells resembling the structures for which they are named (Figure 76.4).

As with most malignancies, adjuvant therapy for yolk sac tumor is based on tumor stage. Different cancer study groups employ different staging systems. However, detailed staging is unnecessary, since the number of patients with metastatic testis tumors in all series is very small, and stratifying response rates and tumor behavior based on the extent of metastatic disease is impossible. Indeed, in large studies, all metastatic yolk sac tumors are treated the same, regardless of the extent or location of metastatic dis-

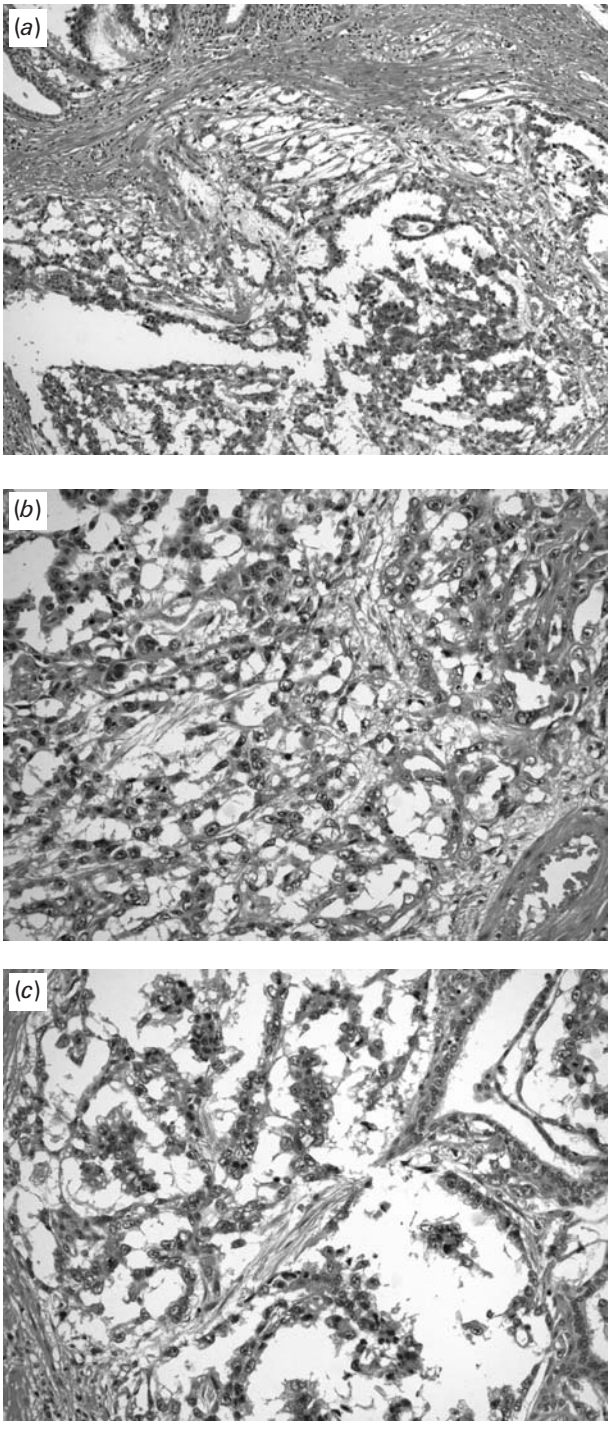

Figure 76.4 Histopathology of a yolk sac tumor; (*a*) ×100 magnification; (*b* and *c*) ×200 magnification.

ease. Therefore, the important distinction for yolk sac tumors is between stage 1 disease (disease limited to the testis and completely excised) and those tumors with any degree of residual or metastatic disease.

The majority of prepubertal testis tumors present with stage 1 disease.[3] Recent studies suggest that these patients can be safely managed with observation followed by chemotherapy for patients who recur.[4–6,22–24] The United Kingdom Children's Cancer Study Group, the German Society of Pediatric Oncology, and the United States Pediatric Intergroup Study (now the Children's Oncology Group) have recently reported their results employing observation for stage 1 yolk sac tumor of the testis and platinum-based chemotherapy for patients with recurrent or metastatic disease.[4–6] Most patients with recurrent or metastatic disease received four cycles of chemotherapy. The potential toxicities of the chemotherapy regimens employed include myelosuppression, ototoxicity and renal toxicity from platinum-based agents, and pulmonary toxicity from bleomycin. High-grade ototoxicity was rare in the United Kingdom study, which utilized carboplatin rather than cisplatin; however, carboplatin is more myelotoxic.

A summary of the three large multicenter studies is presented in Table 76.2. Eighty-four percent of all patients presented with stage 1 disease. Overall, the recurrence rate for patients with stage 1 tumors managed with observation was 17%, and all were cured with chemotherapy. The overall survival of all patients receiving chemotherapy for recurrent or metastatic disease was 98%. Clearly, the outlook for prepubertal testis tumors is excellent. Stage 1 tumors are best managed with orchiectomy and observation. Observation should include frequent chest and abdominal imaging and measurement of AFP levels. Patients with recurrent disease or metastatic disease can expect excellent results with platinum-based multiagent chemotherapy. Future studies will focus on reducing the morbidity for those patients requiring chemotherapy by reducing the number of agents and/or cycles of therapy administered.

Another shift in the management of prepubertal testis tumors has been away from performance of RPLND, once a standard component of management.[25–27] The rationale for this dissection in select adult patients is the likelihood of retroperitoneal disease and the ability to avoid the morbidity of chemotherapy in some patients. Several characteristics of prepubertal tumors argue against its use in children. Most prepubertal patients have clinical stage 1 disease and the recurrence rate for these patients with observation alone is only 17%. Nearly all the recurrences can be salvaged with chemotherapy. For those with metastatic disease, it appears that only a minority of prepubertal patients have disease limited to the retroperitoneum.[28] The majority have disease in the chest (with or without retroperitoneal disease). Finally, the morbidity of abdominal surgery is greater

Table 76.2 Results of three large multicenter studies of pediatric testicular yolk sac tumors

	Number of patients	Percent with stage 1 tumors	Recurrence rate of stage 1 tumors on observation	Chemotherapy for recurrent or metastatic disease	Survival for stage 1 tumors	Survival for those patients with residual disease/ metastases
United Kingdom Children's Cancer Study Group[4]	73	70%	22%	Bleomycin, etoposide, carboplatin	100%	100%
German Cooperative Studies[5]	110	95%	15%	Bleomycin, vinblastine, cisplatin	100%	80%
US Pediatric Intergroup Study[6]	79	82%	18%	Bleomycin, etoposide, cisplatin	100%	100%
Total	262	84%	17%		100%	98%

for children than for adults. Children have a particularly high rate of postoperative bowel obstruction. It is also unclear that a nerve-sparing approach is technically feasible in small children. For prepubertal testis tumors, RPLND is limited to patients with persistent retroperitoneal masses following chemotherapy, an extremely rare occurrence.

Teratoma and epidermoid cyst

Teratoma is the most common benign tumor in prepubertal patients. The median age of presentation is 13 months, with several patients presenting in the neonatal period.[14,29] Histologically, teratomas consist of tissues representing the three germinal layers: endoderm, mesoderm, and ectoderm. Epidermoid cysts are benign tumors composed entirely of keratin-producing epithelium. They are distinguished from dermoid cysts, which contain skin and skin appendages, and from teratomas, which contain derivatives of other germ cell layers. Teratomas and epidermoid cysts are universally benign in prepubertal children. On ultrasonography, most epidermoid cysts appear as discrete intratesticular masses, with areas of increased echogenicity corresponding to the keratin debris or peripheral calcification.[30,31]

At the time of inguinal exploration, an excisional biopsy with frozen section should be performed to confirm the diagnosis.[17,18] In older children with teratoma, surrounding testicular parenchyma must be carefully evaluated. If there is histologic evidence of pubertal changes, then an orchiectomy should be performed since teratomas are potentially malignant in postpubertal males. Biopsies of surrounding testicular parenchyma are probably unnecessary in prepubertal patients.[18,19,30] Whereas 88% of testes removed for adult teratoma contain areas of intratubular germ cell neoplasia, this has generally not been the case for epidermoid cysts or for pediatric teratoma.[16–19]

For patients with epidermoid cyst and prepubertal patients with teratoma, no radiographic studies or follow-up for the development of metastatic disease are required. Because of the potential for malignancy, postpubertal patients with teratoma should be evaluated and followed on the same protocol as adults with potentially malignant germ cell tumors.

Gonadal stromal tumors

Stromal tumors comprise Leydig cell, Sertoli cell, juvenile granulosa, and mixed or undifferentiated tumors. Stromal testis tumors are rare in children, and there are no large series to guide their management. However, anecdotal reports and small series in the literature offer some experience on which to base therapy.[32]

Leydig cell tumors are universally benign in children.[7,32] They usually present between 5 and 10 years of age with precocious puberty. Congenital adrenal hyperplasia (CAH) can also lead to precocious puberty and testicular masses. Patients with Leydig cell tumors typically have elevated testosterone levels with low or normal gonadotropin levels, whereas patients with CAH will usually have elevated levels of 17-hydroxyprogesterone. Leydig cell tumors may be treated by testis-sparing excision.[33] Persistence of androgenic effects may be due to a contralateral tumor, but this is rare in children. Because Leydig cell

tumors are sometimes difficult to detect on physical examination, an ultrasound may be necessary to rule out a contralateral tumor. However, even after successful removal of a solitary tumor, androgenic changes are not completely reversible, and some children may proceed through premature puberty as a result of the activation of the hypothalamic–pituitary–gonadal axis.

Sertoli cell tumors are rare in children. The median age of patients in the Prepubertal Testicular Tumor Registry was 6 months, with a range of 4 months to 10 years.[32] Sertoli cell tumors are usually well circumscribed and often lobulated. Cysts are common. Approximately 10% of adult Sertoli cell tumors are malignant. Sertoli cell tumors are usually hormonally inactive in children, although they may occasionally cause gynecomastia or isosexual precocious puberty. Although all reported cases to date have been benign in children <5 years of age, there have been a few cases of malignant Sertoli cell tumors in older children.[34,35] Orchiectomy is usually sufficient treatment in infants and young children. A metastatic evaluation could be considered in older children and in patients with worrisome histologic findings. When metastatic disease is present, aggressive combination treatment, including RPLND, chemotherapy, and radiation therapy, should be considered.

The large cell calcifying Sertoli cell tumor is a clinically and histologically distinct entity, with a higher incidence of multifocality and hormonal activity.[7,36–39] These tumors are composed of large cells with abundant cytoplasm and varying degrees of calcification, ranging from minimal amounts to massive deposits. Whereas standard Sertoli cell tumors are more common in adults, large cell calcifying Sertoli cell tumors are found predominantly in children and adolescents. Most present with a testicular mass. Approximately one-quarter of patients have bilateral and multifocal tumors. The presence of calcifications results in a characteristic ultrasound appearance including multiple hyperechoic areas.

Approximately one-third of patients with large cell calcifying Sertoli cell tumor have an associated genetic syndrome and/or endocrine abnormality. The two most common associated syndromes are Peutz–Jeghers syndrome, which is characterized by mucocutaneous pigmentation and hamartomatous intestinal polyposis, and Carney's syndrome, which is characterized by myxomas of the skin, soft tissues and heart, myxoid changes of the breast, lentigines of the face and lips, cutaneous blue nevi, Cushing's syndrome, pituitary adenoma, and schwannoma. Screening for these syndromes in patients with large cell calcifying Sertoli cell tumors is important since the patients and their first-degree relatives are at risk for the potentially lethal associated anomalies. Whereas occasionally malignant in adults, large cell calcifying Sertoli cell tumors have been universally benign in patients under 25 years of age, and inguinal orchiectomy is sufficient treatment for children.

Testicular juvenile granulosa cell tumor is a stromal tumor bearing a light-microscopic resemblance to ovarian juvenile granulosa cell tumor. However, the histologic origin of this tumor in testicles is unclear. Granulosa cell tumors occur almost exclusively in the first year of life, most in the first 6 months. Of 22 tumors diagnosed in newborns in the Prepubertal Testicular Tumor Registry, six were juvenile granulosa cell tumors, six were yolk sac tumors, and six were unspecified stromal tumors.[29] Structural abnormalities of the Y chromosome and mosaicism are common in boys with juvenile granulosa cell tumor.[34] Several cases have been described in association with ambiguous genitalia.[40] These tumors are hormonally inactive and benign. Although these children should undergo chromosomal analysis, no treatment or metastatic evaluation is required beyond testis-sparing excision.[32,41]

Undifferentiated stromal tumors consist of areas of gonadal stromal neoplasia and undifferentiated regions of spindle cells that may exhibit a high mitotic rate. These stromal tumors have an epidemiology similar to that of granulosa cell tumors.[32] Although some of these tumors have histologic characteristics commonly associated with malignancy, most behave in a benign fashion. There are inadequate data in the literature to formulate rigid guidelines for managing these tumors. Whereas aggressive behavior has not occurred in young infants, there are reports of such behavior in older children. Unfortunately, histologic features do not appear to correlate with invasive or metastatic potential. Since orchiectomy cures most of these patients, aggressive treatment is probably not appropriate in the absence of radiographic evidence of metastatic disease. However, given the uncertainty, postoperative evaluation and follow-up for the development of metastatic disease seem prudent for patients with this rare tumor.

Gonadoblastoma

Gonadoblastomas are benign tumors that typically arise in dysgenetic gonads. They contain both germ

cell and stromal elements.[42] Dysgenetic or 'streak' gonads are gonads that have failed to develop normally and contain fibrous tissue and primitive ovarian structures. If the gonad has features of primitive testicular development, it is usually referred to as a dysgenetic testis rather than a streak gonad. Gonadoblastoma arises almost exclusively in the dysgenetic gonads of patients with a Y chromosome or evidence of some Y chromatin in their karyotype. Dysgenetic gonads in patients without Y chromatin, such as patients with Turner's syndrome or XX gonadal dysgenesis, seem to be at little risk. Gonadoblastomas have been reported in 3% of true hermaphrodites and in 10–30% of patients with mixed gonadal dysgenesis or pure gonadal dysgenesis in the presence of Y chromatin.[43,44] They also occur commonly in dysgenetic testes.[45]

Although gonadoblastomas are benign, they are prone to the development of malignant degeneration, and overt malignant behavior is seen in 10% of cases.[44] Most cases of malignancy occur after puberty, but there have also been cases reported in children.[44] Therefore, early prophylactic removal of dysgenetic gonads should be performed. If malignant elements are present, a metastatic evaluation should be undertaken. Dysgerminoma (or seminoma) is the most common malignancy to occur in association with gonadoblastoma. Like their counterpart in normal testicles, these tumors are very radiosensitive, and the outlook for these patients is generally favorable.

Testis tumors in congenital adrenal hyperplasia

Congenital adrenal hyperplasia in boys often presents with precocious puberty. Adrenal rests, commonly present along the spermatic cord and in the testicular hilum, may hypertrophy in patients with CAH, leading to testicular nodules that are clinically indistinguishable from testicular tumors. Indeed, the presentation of a testicular mass and precocious puberty is typical of patients with Leydig cell tumors as well. In patients with CAH these nodules are often multifocal and bilateral.[46–48] The diagnosis of CAH can generally be made by demonstrating an elevated serum 17-hydroxyprogesterone level. In this setting, the nodules will usually resolve or significantly reduce in size with steroid replacement. If this occurs, the patient may be followed with serial examinations.[49] Any nodule that fails to respond should be biopsied. Large nodules that fail to regress may be safely enucleated.[49,50]

Leukemia

Historically, the urologist has played an important role in the evaluation of patients with acute lymphoblastic leukemia (ALL) because of the concept that the testis was a site protected from therapy by the 'blood–testis barrier'. Approximately 20% of ALL patients have microscopic involvement at diagnosis, and pretreatment biopsy was common.[51] Following treatment, biopsy was undertaken to detect the 10% of patients with persistent testicular disease. However, with current chemotherapy, most patients with microscopic testicular involvement achieve a complete remission. Conversely, some patients without histologic evidence of testicular involvement at diagnosis will ultimately relapse in the testicles. Therefore, pretreatment testicular biopsy is no longer recommended since it does not predict those at risk for persistent or relapsing disease. Modern treatment has reduced the post-treatment relapse rate to <1%. Therefore, post-treatment biopsy in the absence of clinical evidence of persistent disease is also unnecessary.[52] Rare patients with persistent or recurrent testicular enlargement following chemotherapy should undergo testicular biopsy to confirm the presence of ALL. In most cases the patient will have relapsed at other sites and further systemic treatment will be required. Typically, the testicles are also treated with radiation.

Tumors of the retroperitoneum

77

Gordon A McLorie and Darius J Bägli

Introduction

Retroperitoneal tumors of non-renal origin are relatively uncommon in children. The most significant are neuroblastoma, sacrococcygeal teratoma, the rare childhood pheochromocytoma, and adrenal carcinoma. This chapter will focus on these four tumor types, with primary emphasis on the first two. The listing given in Table 77.1 of non-renal retroperitoneal tumors is included for completeness.

Neuroblastoma

Neuroblastoma accounts for 8–10% of all childhood cancers. Following the original description by Virchow in 1864, it has continued to capture the imagination and interest of pediatricians, surgeons, and scientists. Historic landmarks in the biology of neuroblastoma include the understanding of the relationship of this childhood malignancy to the secretion of neuroactive substances in 1957, followed by the ability to establish a biochemical diagnosis based on the urinary secretion of catecholamines. Cushing described its transition in biologic activity from a malignant tumor to one of a benign nature, whereas Beckwith and Perrin[1] noted that clusters of neuroblastic nodules resembling neuroblastoma in situ were an incidental finding in the adrenal glands in children dying of other diseases. These clues provided the initial impetus that led to the recognition of the now well-known phenomenon of spontaneous regression of some neuroblastomas. Newer advances in molecular research have provided significant further insight into the biology of neuroblastoma. Furthermore, the paradigms described for neuroblastoma have acted as a template for diagnostic staging and applications of molecular and genetic insights to clinical therapies of other childhood malignancies. Fingerprinting the tumor's molecular characteristics (beyond *MYCN* proto-oncogene expression) has allowed stratification of children with neuroblastoma into distinctive clinical subsets. These stratification and staging methodologies provide better applications of therapeutic options and appropriate balancing of therapies that are more aggressive to children with poor prognostic disease. They also allow us to pursue a goal of less aggressive therapies to be used for those children in whom better prognosis can be defined.[2]

Recent insights have unfolded as a result of neonatal screening programs in Japan and Canada. In these programs, the secretion of urinary vanillylmandelic acid (VMA) in the newborn has been used as a method of neuroblastoma detection. However, early detection has neither reduced the occurrence nor improved the prognosis of those children who are discovered to have higher-grade tumors in later infancy and childhood. This has led to the thesis that the tumors detected during neonatal screening programs are those that have a natural propensity for spontaneous resolution.[3,4] The results suggest that mass screening for neuroblastoma, while feasible, is unlikely to alter the course of those patients destined to succumb to the disease.

Table 77.1 Non-renal retroperitoneal tumors

Benign	Malignant
Lymphangioma	Neuroblastoma
Neurofibroma	Pheochromocytoma
Ganglioneuroma	Sacrococcygeal teratoma
Lipoma	Non-genitourinary pelvic rhabdomyosarcoma
Sacrococcygeal teratoma	Lymphoma
	Liposarcoma
	Fibrosarcoma
	Leiomyosarcoma
	Malignant fibrous histiocytoma
	Secondary tumors

Clinical and biologic features

Neuroblastoma ranks as the most common extracranial solid malignancy of childhood[5] and early infancy. The incidence may be increasing slightly.[5,6] In children presenting with neuroblastoma, 65% will occur in the retroperitoneum, of which 40% will originate in the adrenal gland.[7]

Few, if any, environmental risk factors have been identified for neuroblastoma. Recently, maternal vaginal infections, their treatment, and prenatal maternal hormone use have been weakly suggested to increase the risk of neuroblastoma in offspring.[8] Pesticide exposure has been suggested as being associated with an increased risk of carcinogenesis in children compared with adults; the risk included, but was not specific for, neuroblastoma.[9]

While newer molecular modalities are helping to refine prognostic groupings and treatment assignment, the overwhelming variables distinguishing high from low-risk groups continue to be age at diagnosis, tumor stage, and histologic grade.[10] Diagnosis before 12 months of age is more clinically favorable than later diagnosis.

Any predisposition for neuroblastoma appears to follow an autosomal dominant pattern, as elucidated by the two-hit hypothesis of Knudson and Strong.[11] Also described for Wilms' tumor and pheochromocytoma, inherited forms of neuroblastoma may occur in patients who harbor a mutation in a gene that preexisted in a parental germ line (preconception or germinal mutation). A subsequent spontaneous mutation of the other copy of the same gene (a somatic mutation) in a cell of the appropriate background (neural crest cell) leads to malignant transformation of that cell. This has led to estimates that over one-fifth of all neuroblastoma may be of the inherited variety.[11] The occurrence of non-familial neuroblastoma must therefore await these two critical mutations or 'hits' as two independent spontaneous events. This explains the reduced likelihood (incidence) of non-familial or sporadic disease. With one of two mutations possibly present in all cells of a given child with a strong family history of neuroblastoma, it is easy to see why earlier incidence, bilaterality and multifocality, and higher recurrence rates are the norm in those with familial disease. Exceptions to the two-hit hypothesis have been reported (familial neuroblastoma in older children), suggesting that other genetic mechanisms may also underlie familial disease.[12] While several reports exist of neuroblastoma being found in children with a chromosomal abnormality, few chromosomal predispositions have been definitively associated with neuroblastoma. Abnormal rearrangements have been described involving chromosomes 1 and 17 (see below). Deletions involving 1p36 have implicated this region as containing a neuroblastoma tumor suppressor gene, and gains in the 17q region have been associated with poor prognosis.[12–17] In addition, FISH analysis for chromosome alteration in 3p and 11q may define patients with a poorer prognosis.[18] Finally, loss of heterozygosity (LOH), a molecular phenotype characterized by the loss of the subtle differences that normally exist between the two allelic (parental) copies of any gene signifying that one of the copies is missing, has been identified as a more general phenomenon in neuroblastoma. Subjects with LOH are, therefore, homozygous instead of heterozygous for that particular chromosomal region. When a disease becomes evident in association with LOH in particular regions of a chromosome, this implies that the missing region of that chromosome encodes a gene or genes responsible for suppressing that disease, i.e. tumor suppressor genes. Although LOH does not identify the missing gene itself, LOH in neuroblastoma has been reported in a number of chromosomes, including 1p, 11q and 14q, 2q, 9p, and 18q.[19]

Clinical manifestations: primary, metastatic, and paraneoplastic features

The presenting signs and symptoms are variable and may reflect the effects of the tumor, the presence of metastatic disease, or the results of tumor hormone production. As mentioned earlier, prenatal screening may also identify neuroblastoma. Infants may present with an abdominal mass that is often huge. In spite of the size, which makes the tumors detectable at birth, their prognosis is often excellent with respect to cure, although some neurological defects may persist.[20] A unique feature of neuroblastoma in children is the potential for widespread liver metastatic disease that may signify stage 4S disease (Figure 77.1).

Children with stage 4S have a potential survival rate of up to 90%, in spite of metastases to either liver, skin, or bone marrow, but not to cortical bone. Subcutaneous nodules are another manifestation of this early presentation.[22] In some patients, tumors regress spontaneously. Alternatively, metastases may regress following excision of the primary tumor.[23–25] In children >1 year of age the size of the abdominal mass is variable and may not be the presenting symptom. Malaise and/or pain reflecting the presence of

Figure 77.1 Neuroblastoma metastatic to liver. Stage 4S neuroblastoma underwent spontaneous regression. (Reproduced from Snyder et al,[21] with permission.)

metastatic disease is the presenting complaint in up to 60%. Anemia (from bone marrow involvement in 50% of patients) is also a common presenting sign. The new or sudden onset of constipation or urinary retention may herald the well-known propensity of neuroblastoma to invade the spinal cord. In addition, transient pain attributable to bony metastases may mimic rheumatoid arthritis. Lung or brain metastases are common sites of relapse and late-stage disease.

Paraneoplastic syndromes occur in fewer than 5% of neuroblastoma patients. Intractable diarrhea may result from the secretion of vasoactive intestinal peptide (VIP).[26] However, this symptom, mimicking malabsorption syndrome, is more often associated with the better-differentiated ganglioneuroma or intermediately differentiated ganglioneuroblastoma. Resolution follows removal of the tumor. Another unusual symptom is cerebellar ataxia and opsomyoclonus (dancing feet, dancing eyes; myoclonic encephalopathy of infants). This syndrome is of unknown pathogenesis and is more often associated with thoracic tumors.[7] Whereas symptoms of catecholamine excess (palpitations, tachycardia, and hypertension) are rare in neuroblastoma, they can occur from excess circulating tumor-derived norepinephrine. However, norepinephrine is less potent than its metabolite, epinephrine, in inducing these symptoms. These symptoms are more commonly found in patients with pheochromocytoma where the enzyme responsible is phenylethanolamine *N*-methyltransferase (PNMT), which catalyzes the conversion of norepinephrine to epinephrine.

Gross, histologic, molecular pathology, and markers

Neuroblastomas arise from cells of neural crest origin, which ultimately form the sympathetic nervous systems (sympathogonia). The sites of origin may be found at any location in the sympathetic nervous system with over one-half occurring in the neonatal abdominal cavity, and up to two-thirds from the adrenal gland. The remainder occurs in the sympathetic ganglia and, more rarely, in the organ of Zuckerhandl. The spectrum of biologic behavior or potential of these tumors is broad. Malignant neuroblastomas constitute the majority. Ganglioneuroblastoma and ganglioneuroma represent progressively more benign forms of the tumor, reflecting more indolent clinical manifestations, better prognoses, as well as distinct morphology and biochemical profiles.

The histopathologic features that define the malignant potential are unique. Homer Wright pseudorosettes, the diagnostic histologic presence of eosinophilic neutrophils surrounded by neuroblasts, occur in only one-half of cases.[27] The presence of associated neuropils (pigmented neuritic processes) is pathognomonic for neuroblastoma. The other type of cell is the Schwann cell, which may be recruited into the tumor and constitutes the schwannian stroma, which makes up the mesenchymal component of the tumor. The degree of histologic differentiation is classified according to a variety of schemes but the most popular is that developed by Shimada, which has recently been revised by Joshi (Table 77.2), and a combination of the two is the basis of planned prospective trials.[29]

Molecular pathology

Molecular understanding of neuroblastoma has identified several newer features of the disease that may aid in all aspects of its management, including diagnosis, natural history, prognostic stratification, and treatment selection. These include analyses of nuclear and chromosomal material, and neuronal phenotyping through assessment of various neuron-associated

Table 77.2 Histopathologic classifications of Shimada and Joshi

Prognosis	Histopathologic features/age
Favorable	
Shimada	Stroma rich, all ages, no nodular pattern
	Stroma poor, age 1.5–5 years, differentiated, MKI <100
	Stroma poor, age <1.5 years, MKI <200
Joshi	Grade 1, all ages; grade 2, <1 year
Unfavorable	
Shimada	Stroma rich, all ages, nodular pattern
	Stroma poor, age >5 years
	Stroma poor, age 1.5–5 years, undifferentiated
	Stroma poor, age 1.5–5 years, differentiated, MKI >100
	Stroma poor, age <1.5 years, MKI >200
Joshi	Grade 2, age >1 year; grade 3, all ages

Grade 1 = low mitotic rate (<10 mitotic figures per 10 high power fields) and calcification present; grade 2 = either low mitotic rate or calcification present; grade 3 = neither low mitotic rate nor calcification present.
MKI = mitosis–karyorrhexis index (number of mitoses and karyorrhexis per 5000 cells).
Adapted from Brodeur and Castleberry,[28] with permission.

growth factors. Whereas karyotyping has identified specific chromosomal abnormalities (see below), analysis of DNA ploidy has also revealed significant information. Paradoxically, neuroblastomas of the hyperdiploid variety are more likely to respond favorably to chemotherapy. Diploid or near-diploid tumors are associated with higher-stage disease (including unresectable tumors), poorer prognosis, a lower response to chemotherapy, and recurrence or progression.[30–33]

The most widely reported genetic marker for neuroblastoma has been amplification of the *MYCN* (or N-myc) proto-oncogene.[24,34] The association between *MYCN* amplification and high-grade,[35] advanced stage disease at presentation, rapid progression, and overall poor prognosis is well established. Recently, an etiologic relationship between *MYCN* and neuroblastoma has been demonstrated by two complementary studies. Chan and co-workers from the Hospital for Sick Children in Toronto reported that elevations in MYCN protein expression in neuroblastoma tissues is independently associated with poor prognosis in high-stage disease (III, IV, IVS) even in the absence of *MYCN* gene amplification.[36] Furthermore, MYCN protein levels were prognostic, independent of the most significant clinical variables of age or stage,[36] thus strongly supporting the concept that *MYCN* expression is directly involved in the cellular events of neuroblastoma progression. Conversely, in the subgroup of patients who did well with normal *MYCN* gene expression, MYCN protein levels were undetectable.[36] In a related animal study, the targeted overexpression of the *MYCN* gene in neuroectodermal cells led to the development of neuroblastoma in *MYCN* transgenic mice.[37] MYCN tumorigenesis is further augmented in the absence of the recognized tumor suppressor genes *NF1* or *RB1*.[37] This demonstrates that *MYCN*'s transforming effect can be influenced by other genes, which is consistent with the emerging concept of multistep processes in malignant transformation. MYCN gene amplification is present in approximately 40% of patients with advanced stage III or IV disease (compared with <10% in low-stage patients) and its absence augurs a slower disease progression in these patients.

A recent report by Wei et al[38] at the National Cancer Institute has proposed an artificial neural network to define 19 predictable genes which would substratify prognosis groupings beyond *MYCN* amplification. Also, Weber et al[39] has shown that coexpression of insulin receptor-related activity and insulin-like growth factor correlated with enhanced apoptosis and differentiation in neuroblastomas.

As mentioned above, deletions of chromosome 1 and gains in chromosome 17 have been shown to carry strong prognostic information in advanced neuroblastoma. A landmark report from a collaborative group in Europe has shown a very powerful association between gains in chromosome 17q and adverse neuroblastoma outcome. The study is important because of its large numbers, the availability of all clinical and genetic data variables for 85% of the patients in the cohort, and the close coordination between a team of basic and clinical researchers. In total, 313 children from six European centers were studied. Often, but not exclusively, the gain of 17q was linked to the loss of 1p. Most significantly, in univariate and multivariate analyses, 17q gain was independently predictive of poor outcome (30.6% 5-year survival with 17q gain vs 86% 5-year survival without

Table 77.3 Genetic neuroblastoma profiles

Feature	Type 1	Type 2	Type 3
MYCN amplification	None	None	Present
DNA ploidy	Hyperdiploid	Near-diploid	Near-tetraploid
LOH	Rare	25–50%	Present
Neurotropin gene expression	High	Low/absent (except TRK-B, high)	
Age	1 year	>1 year	
Stage	1, 2, 4S	3, 4	
3-year survival	95%	25–50%	<5%

LOH = loss of heterozygosity; TRK = tyrosine kinase receptor.

17q gain).[40] Prognosis may be further predicted by more chromosome changes on 3p and 11q.[18]

A long-standing notion in tumorigenesis states that transformation (neoplasia) is the result of aberrant differentiation pathways leading away from the normal cell phenotype. As a result, neuroblastoma may represent an aberration of normal neuronal development. As such, several neuronal differentiation markers have been investigated in this disease, including chromogranin A, neuropeptide Y, and receptors for neurotropins such as nerve growth factor. Neuropeptide Y is detectable in abundance in the serum of neuroblastoma patients and may be useful in following tumor burden both before and after therapy.[41] In tumor tissue, it reaches its highest levels in poorly differentiated neuroblastoma, compared with ganglioneuroblastoma or ganglioneuroma.[41] Conversely, chomogranin A derivatives may become useful markers of more favorably differentiated tumors.[41]

Acting through various receptors, neurotropic factors are, by definition, involved in the differentiation of neural tissues. One family of neurotropin receptors, the tyrosine kinase receptors TRK-A, TRK-B, and TRK-C, is showing promise in understanding neuroblastoma biology. It appears that *TRK-A* gene expression is associated with favorable outcome, yielding its highest expression in more well-differentiated tumors.[42,43] Furthermore, TRK-A levels are inversely correlated with *MYCN* gene expression.[42] Expression of TRK-C and shortened forms of TRK-B also portend better outcome.[42] Together, these observations have also led to speculation that functioning, intact neurotropin/TRK receptor pathways in these tumors may be further linked to their propensity to mature (differentiate) into ganglioneuromas, or regress through a cell-death pathway (from a presumed eventual unavailability of factor for the receptor, or receptor malfunction). However, as our knowledge of the role of these pathways evolves, it is becoming clear that they carry potential as powerful markers of disease, or even as molecular therapeutic targets to manipulate neuroblastomas to assume differentiation or regression pathways.

Drawing on the foregoing discussion, neuroblastomas may be stratified into specific prognostic subgroups based on the genetic interplay represented by *MYCN* expression, LOH, DNA ploidy, and neurotropin receptor expression. Combined with age and stage, three genetic neuroblastoma profiles can be determined with differing survival rates (Table 77.3).

Diagnosis, staging, and treatment

The diagnosis of neuroblastoma is confirmed by histologic sampling of tumor tissue or bone marrow. Standard light and electron microscopic evaluation may be followed by immunohistochemical identification of tissue of neuronal origin. The vast majority of the tumors secrete catecholamines synthesized from the amino acid tyrosine in the sequence: dopa, dopamine [both excreted as homovanillic acid (HVA)], and finally norepinephrine. In contrast to pheochromocytomas, neuroblastomas lack the ability to convert norepinephrine to epinephrine. Norepinephrine and epinephrine are both excreted as VMA.

Imaging techniques

Traditionally, the presentation of an abdominal neuroblastoma has been either by the discovery of an abdominal mass on physical examination, or the result of investigations to explain symptoms related to either metastatic disease or the neurendocrine manifestations of the tumor. Abdominal ultrasonography will detect a great percentage of those tumors that occur in the abdominal cavity. Occasionally they are

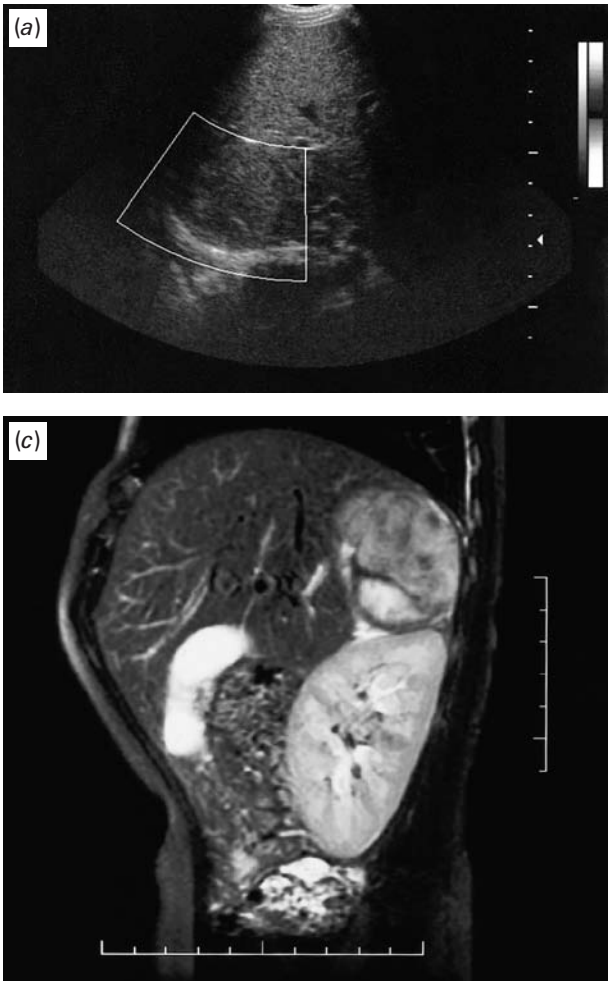

Figure 77.2 (*a*) Ultrasound image of a neuroblastoma discovered in a 1-year-old child as 'incidentaloma' in the course of investigating contralateral antenatally diagnosed hydronephrosis. A prior sonogram 6 months earlier with good views of the same area showed no evidence of mass lesion. (*b* and *c*) Transverse and sagittal magnetic resonance images of the same lesion, showing relationships in the retroperitoneum.

found as an incidental finding in the course of pursuing an otherwise unrelated symptom. With increased sonographic screening this has now become a more common cause for presentation of these tumors.[45] In the authors' recent experience at a large children's hospital there have been two instances in the past year when children who were being followed in the course of an investigation for antenatal hydronephrosis had neuroblastomas that became apparent and had not been present on prior examinations (Figure 77.2).

Diagnostic imaging techniques are evolving and improving with great rapidity, and there is no consensus as to which method is best. The choices include ultrasonography, computed tomography (CT), and magnetic resonance imaging (MRI). The availability and the non-invasive nature of ultrasonography endorse this technology as the choice for the initial screening test. The time required for both CT and MRI makes their selection for young children more critical. Either of these techniques may be used to delineate and define the extent of the disease. Availability may be the most critical determinant of which technique should be used (Figures 77.2 and 77.3).

In seeking metastatic disease a chest radiograph is a useful initial step. Radioisotope bone scanning using

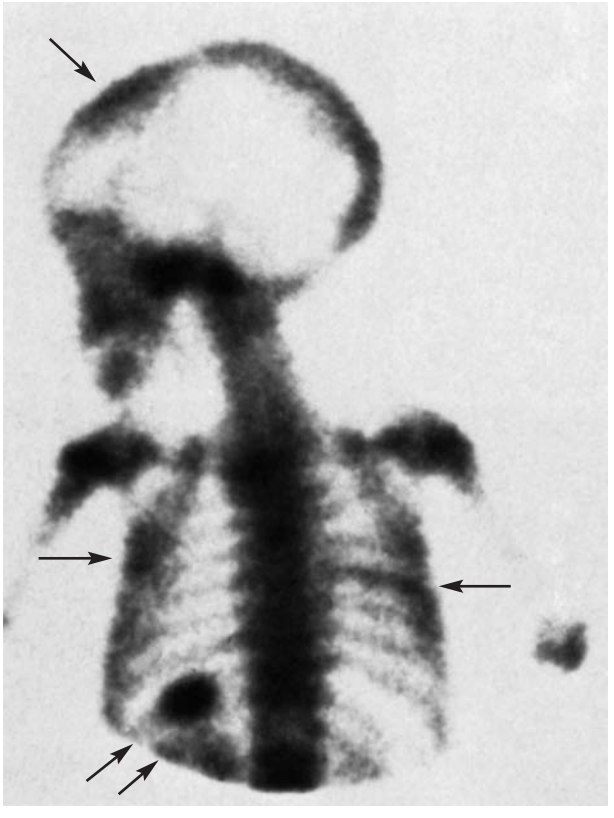

Figure 77.4 Posterior view of thorax and skull. Increased uptake is seen in skull, upper thoracic spine and left and right ribs (arrows) as a result of metastatic neuroblastoma. The decreased uptake at T12 is an unusual manifestation of metastatic tumor. The right suprarenal uptake of tracer is within the primary tumor (double arrow).

technetium 99m (^{99m}TC)-methylene diphosphonate is more accurate than a standard X-ray skeletal survey for the detection of bony metastases (Figure 77.4).

Prognostic markers

Both clinical and biochemical markers have evolved that are helpful in the management of neuroblastoma. The best recognized are the traditional clinical parameters of age at diagnosis and tumor stage. Patients diagnosed at 1 year of age appear to show consistently better survival outcomes than older children, even in the presence of advanced disease at presentation. Survival also stratifies dramatically with respect to disease stage, with 75–90% 5-year survival for stage 1, 2, and 4S patients, compared with 10–30% 2-year survival for stage 3–4 disease.

Various biochemical and cell-associated parameters have also been assessed for their prognostic ability in the management of neuroblastoma. Serum ferritin is elevated during periods of rapid tumor growth and/or large tumor burden. Whether this reflects a growth requirement for ferritin by the tumor or is a product of neuroblastoma cell metabolism is unknown. Ferritin levels appear to discriminate between stage 4 and stage 4S disease.[46] Lactate dehydrogenase (LDH) is elaborated non-specifically in several tumor types, including neuroblastoma, where it may reflect rapid tumor cell turnover and tumor burden.[47] Neuron-specific enolase is a cytoplasmic enzyme found in cells of neural origin.[48] Neuroblastoma prognosis appears worse if elevated levels are detected in serum, although this marker is not specific to neuroblastoma.[48] Serum and tissue ganglioside GD2 is a glycosphingolipid shed by neuroblastoma tumor cells. It may reflect tumor burden, and decreasing levels may be seen as a positive response to successful reduction of tumor load. The presence of GD2 on the cell surface has attracted interest in targeting this molecule using immunotherapy strategies.[49–51] Finally, matrix metalloproteinases (MMPs) are cellular enzymes required to break down the extracellular matrix and facilitate cell movement through the matrix during the metastatic process. Very recently, tumor cell expression of a membrane-associated MMP was found to correlate with advanced stage and poor outcome in neuroblastoma.[47]

Staging

A disease with such diverse manifestations as neuroblastoma in childhood needs a comprehensive staging system to allow precise diagnostic criteria and a method for categorizing and quantifying disease. Such a staging system then acts as a template upon which diagnostic criteria can be applied to various subgroups of disease, and permits definition of outcome measures that will allow collaboration between centers in implementing and assessing clinical trials. An international working group published the outcome of its deliberations in 1988.[52] The staging system recommended is known as the International Neuroblastoma Staging System (INSS) and the response criteria are referred to as the International Neuroblastoma Response Criteria (INRC). This staging system has now replaced previous systems by Evans, originally established by the Pediatric Oncology Group (POG). Table 77.4 outlines the three staging systems, thus facilitating some comparison of previously published data.

Treatment

Therapy of neuroblastoma requires close coordination of medical, surgical, and radiation oncologists

Table 77.4 Neuroblastoma staging systems

Evans and D'Angio	POG	INSS
Stage I Tumor confined to the organ or structure of origin *Stage II* Tumor extending in continuity beyond the organ or structure of origin but not crossing the midline. Regional lymph nodes on the ipsilateral side may be involved *Stage III* Tumor extending in continuity beyond the midline. Regional lymph nodes may be involved bilaterally *Stage IV* Remote disease involving the skeleton, bone marrow, soft tissue, distant lymph node groups, etc. (see stage IV–S) *State IV–S* Patients who would otherwise be stage I or II, but who have remote disease confined to liver, skin, or bone marrow (without radiographic evidence of bone metastases on complete skeletal survey)	*Stage A* Complete gross resection of structure of origin/primary tumor, with or without microscopic residual. Intracavitary lymph nodes, not adhered to and removed with primary (nodes adhered to or with tumor resection may be positive for tumor without upstaging patient to stage C), histologically free of tumor. If primary in the abdomen or pelvis, liver histologically free of tumor *Stage B* Grossly unresected primary tumor. Nodes and liver same as stage A *Stage C* Complete or incomplete resection of primary. Intracavitary nodes not adhered to primary histologically positive for tumor. Liver as in stage A *Stage D* Any dissemination of disease beyond intracavitary nodes (i.e. extracavitary nodes, liver, skin, bone marrow, bone) *Stage DS* Infants <1 year of age with stage IV–S disease (see Evans and D'Angio)	*Stage I* Localized tumor with complete gross excision without microscopic residual disease; representative ipsilateral lymph nodes negative for tumor microscopically (nodes attached to and removed with the primary tumor may be positive) *Stage 2A* Localized tumor with incomplete gross excision; representative ipsilateral non-adherent lymph nodes negative for tumor microscopically *Stage 2B* Localized tumor with or without complete gross excision, with ipsilateral non-adherent lymph nodes positive for tumor. Enlarged contralateral lymph nodes must be negative microscopically. *Stage 3* Unresectable unilateral tumor infiltrating across the midline, with or without regional lymph node involvement; or localized unilateral tumor with contralateral regional lymph node involvement; or midline tumor with bilateral extension by infiltration (unresectable) or by lymph node involvement *Stage 4* Any primary tumor with dissemination to distant lymph nodes, bone, bone marrow, liver, skin, and/or other organs (except as defined for stage 4S) *Stage 4S* Localized primary tumor as defined for stage 1, 2A, or 2B with dissemination limited to skin, liver, and/or bone marrow (limited to infants <1 year of age)

POG = Pediatric Oncology Group; INSS = International Neuroblastoma Staging System.
From Halperin et al.[53]

and clearly represents a prime example of multimodal cancer therapy. Surgical intervention plays a dual role. At the time of diagnosis, open or laparoscopic approaches may be necessary to obtain adequate and thorough samples for histologic and molecular diagnosis and marker analysis. Needle biopsy materials are most often inadequate for these purposes. For selected tumors, primary surgical excision

may be possible, particularly for small, locally confined cases. In this regard, laparoscopic surgery may be considered and has been used successfully for small tumors identified by screening.[54] Laparoscopy is safe and feasible for adrenal tumors.[55] Given that infant screening detects tumors that are generally biologically favorable, laparoscopic surgery may be a safe modality on oncologic grounds. Open surgical dissection is also employed to both assess response to therapy and excise residual disease after initial courses of chemotherapy have been completed. Recent reports have suggested a higher incidence of nephrectomy in children with neuroblastoma who were treated with primary surgical intervention.[56]

Chemotherapy is a major component of the treatment of neuroblastoma. Both single-agent and synergistic multiagent drug regimens are used, combining cell-cycle-specific and cell-cycle-independent drugs to achieve the maximum ratio of therapeutic benefit to toxicity. Ionizing radiation has a role in neuroblastoma treatment as the tumor is radiosensitive. It is most useful in achieving local control on the one hand, and palliation of disease uncontrollable by other modalities on the other. As a primary modality, however, radiotherapy is limited by the extensive metastatic proclivity of many neuroblastomas. The agent metaiodobenzylguanidine (MIBG), used in the localization of neuroblastomas and pheochromocytomas, has been studied for its ability to bind to neuroblastoma tumors systemically and carry with it radioligands such as iodine-131 that are toxic to the tumor cells.[51,57,58] This approach has also been used as a surgical adjunct to guide tumor tissue resection using the gamma camera intraoperatively once the tumor is radiolabeled by preoperative injection of [I^{131}]MIBG.[59]

Given the aggressive nature of advanced and higher staged disease, efforts continue to attempt improved disease control in this subset of patients while refining therapy to limit toxicity in lower stage and more favorable disease.

Treatment strategy

The ability to stratify patients into distinctly risk-related groups, by application of the varied but highly accurate histologic and molecular diagnostic and staging methodologies, has permitted the much more judicious and specific use of the therapeutic regimens.

Stage 1 and 2 tumors (low risk) are treatable by primary surgical resection alone, with no need for initial chemotherapy or radiotherapy. A prognosis of up to 89% survival has been reported in this group of patients.[2,58,60] Kushner et al[61] have shown that excellent results (80 to survival) can be achieved even with reduction in the number of chemotherapy cycles from 7 to 5. In another report, the same authors[62] have shown that surgery alone is a potentially curable treatment for recurrent disease. Stage 4S tumors will undergo spontaneous remission and are thus considered low risk. However, if symptoms are present related to severe hepatic metastatic disease or respiratory compromise, patients may benefit from chemotherapy or radiation therapy in small doses.

Stage 3 tumors (intermediate risk) still have an excellent overall survival rate of up to 89%[60] but chemotherapy is advised following primary surgical excision. Second-look surgery may also be appropriate after chemotherapy. The goal of therapy in this group is to reserve more intense therapy for those children with biologically unfavorable tumors.

Patients with stage 4 disease (high risk) have derived minimal benefits from even the most intensive regimens. Multiagent chemotherapy remains the standard primary treatment strategy for these patients. Only a number of adolescents have developed stage 4 neuroblastomas and their prognosis remains poor.[63] There have been isolated applications of ablative chemotherapy and bone marrow transplantation and these intensive therapeutic approaches are currently being explored in multicenter trials. The overall prognosis in this group of children remains very low (15–35% survival).[64] An additional risk of bone marrow transplant is Epstein–Barr virus-related lymphoproliferative disease (EBV-LPD). Powell et al[65] from the Children's Hospital of Philadelphia outlined an incidence of 4% of neuroblastoma patients who received a bone marrow transplant and developed EBV-LPD. Treatment of the lymphoprofilerative disease was successful in four of the five patients.

Ganglioneuroma

A more histologically benign counterpart of neuroblastoma is the ganglioneuroma. Ganglioneuroblastoma is an intermediate malignant classification between ganglioneuroma and neuroblastoma, and for treatment purposes is regarded with neuroblastoma. Ganglioneuromas are most often seen in older children and present as abdominal masses. It is intriguing to hypothesize that late development of a more benign variant may represent a 'second hit', but these tumors do not exhibit an 'explosive' form of metastatic behavior.[66] Nonetheless, by virtue of their inexorable growth and distortion

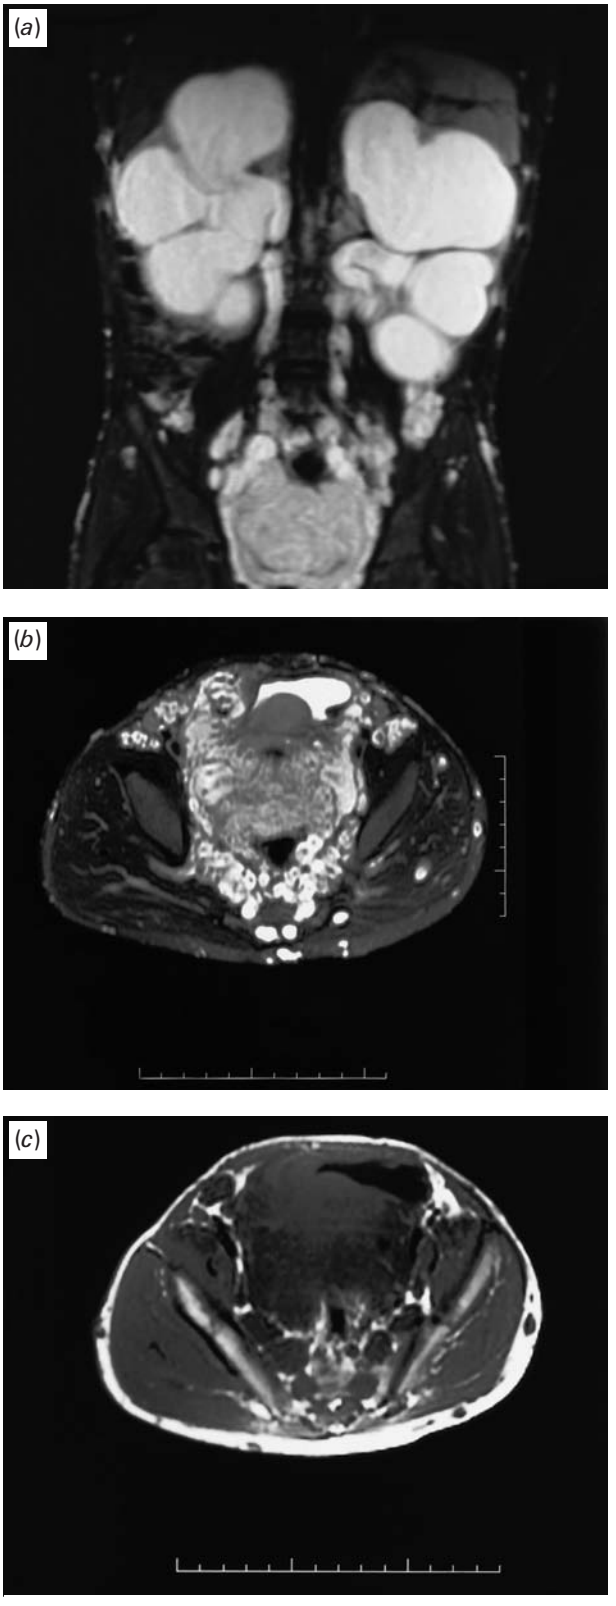

Figure 77.5 (*a*) Magnetic resonance scan of patient with a ganglioneuroma, showing obstruction of the ureters. (*b*) Primary neuronal masses displacing the bladder anteriorly and the rectum posteriorly. (*c*) T2-weighted image of the same pelvic area as in (*b*), showing the different appearance of neural tissues.

Figure 77.6 Pathologic section of area of excised ureter, with ureter encased in, but not invaded by tumor tissue.

of adjacent tissues they can have a very morbid clinical course. Such a case is illustrated in Figure 77.5, in which both gastrointestinal and genitourinary tissues are grossly displaced. The urologic system, in particular, may exhibit such profound destruction that urinary diversion may be deemed necessary. The figures illustrate the results of MRI, which can provide eloquent detail of the soft-tissue involvement by these tumors, while there is no evidence of direct histologic invasion of the compressed tissues (Figure 77.6).

The correlation of the MRI features with latent malignant potential in these tumors has been documented by Ichikawa et al.[67] They were able to show that punctate calcification on the CT scan and low or intermediate attenuation are common in ganglioneuromas. The MR images are mainly of low intensity on T1-weighted images (T_1WI) and of high intensity on T2-weighted images (T_2WI). Dynamic MR studies show a lack of early involvement but gradually increasing enhancement. The authors concluded that the absence of these features, judged 'typical' for ganglioneuroma, should suggest a potential for a more malignant course. The slow-growing nature of ganglioneuromas may also have a devastating effect on vascular and neurologic function by virtue of its compressive effects on adjacent structures. Figure 77.7 demonstrates extension along the sacral nerve prior to

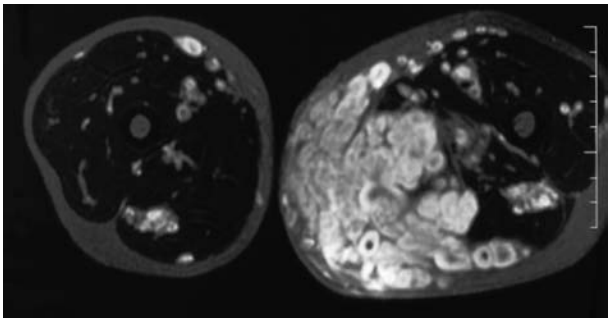

Figure 77.7 Extension of ganglioneuroma down the sheath of the sacral nerve.

the appearance of clinical degeneration. This and other cases have demonstrated the potential for clinical morbidity that may be associated with ganglioneuroma despite its non-metastatic nature. To prevent these localized effects, incomplete surgical resection may be justified in the absence of effective chemotherapy or radiotherapy.

Pheochromocytoma

Clinical features and presentation

Pediatric pheochromocytoma is an extremely uncommon primary tumor of the adrenal medulla, although it is the most common hyperfunctioning form of this tissue in children. Over a period of 5 years at the Hospital for Sick Children in Toronto, of 30 patients presenting with a primary adrenal tumor, only one, a 16-year-old girl, had a pheochromocytoma (pers comm). The tumors arise in the autonomic system, with 90% originating in the adrenal gland. Catecholamine production is the norm and is the basis for both the clinical manifestations and laboratory diagnosis. Pediatric pheochromocytomas can be seen in association with a variety of diseases including neurofibromatosis, von Hippel–Lindau disease, Sturge–Weber syndrome, and multiple endocrine neoplasias (MEN-2). Those associated with MEN-2 are more likely to occur later in life and are more likely to be bilateral. Almost 25% of patients with apparently sporadic pheochromocytoma may be carriers of the mutations, thus justifying an in-depth analysis.[68]

Imaging, biochemical features, and new prognostic markers

The diagnosis of pheochromocytoma in childhood is suggested by the rare coexistence of hypertension and abdominal mass detectable on sonographic evaluation. Non-palpable pheochromocytoma causing secondary hypertension in children is exceedingly rare. The diagnosis is confirmed by means of either serum or urine confirmation of hypersecretion of catecholamines.

As stated previously, the principal catecholamine that produces the classic characteristic symptoms of flushing, palpitations, hypertension (vasoconstriction), and anxiety in patients with pheochromocytoma is epinephrine. Epinephrine is a metabolite of its precursor, norepinephrine. The latter is a less potent mediator of the clinical constellation seen in pheochromocytoma. However, compared with neuroblastoma, both catecholamines are more commonly produced by pheochromocytomas. Pheochromocytomas, particularly those of adrenal origin, produce the enzyme PNMT, which catalyzes the conversion of norepinephrine to epinephrine. As such, the norepinephrine to epinephrine ratio has been used to distinguish pheochromocytomas of adrenal from those of extraadrenal origin. Weise et al[69] have recently endorsed the sensitivity of the ratio of free metanephrines, and this has been confirmed by others.[70]

With respect to diagnostic imaging, the initial methodology in suspected cases is ultrasonography (Figure 77.8). Thereafter, either CT or MRI can be employed to confirm the diagnosis of an adrenal or a

Figure 77.8 Ultrasound image of a left suprarenal tumor in a 16-year-old child presenting with hypertension.

Figure 77.9 Computed tomographic image of left suprarenal pheochromocytoma, as seen in ultrasound in Figure 77.8.

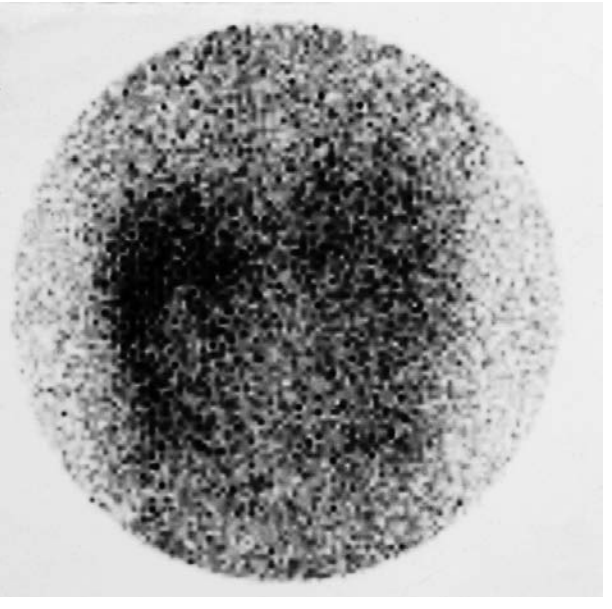

Figure 77.10 MIBG abdominal scan, with uptake of radionuclide in the left suprarenal area, in a 16-year-old patient with pheochromocytoma.

para-adrenal mass (Figure 77.9). Serologic or creatinine-specific measures of catecholamine excretion in the urine are then undertaken. The most specific diagnostic imaging methodology is radionuclide scanning using [I^{131}]MIBG scintigraphy (Figure 77.10). With this approach, the sensitivity is greater than 90%.[71] [I^{131}]MIBG scanning is particularly valuable in the localization of tumors that are outside the adrenal gland.[72,73]

One of the persisting challenges in pheochromocytoma management remains the inability to define precisely whether a given tumor is benign or malignant. The current gold standard criterion for malignancy remains the appearance of metastases. As a predictor of malignancy, this is analogous to predicting that automobile brakes are defective based on the occurrence of a collision. Clearly, more accurate markers for determining malignancy of pheochromocytoma are needed. Recent studies have identified biologic features of pheochromocytomas that may hold promise in determining the metastatic proclivity of the tumor. For example, telomeres comprise repeated nucleotide sequences on the ends of chromosomes. During normal cell aging, they progressively shorten with successive normal cell replications. In normal cells, this shortening is thought to be associated with waning activity of the enzyme that produces the telomeres. Recent retrospective molecular analysis of pheochromocytoma tumors known to be benign or malignant reveals that telomerase, the RNA polymerase enzyme responsible for the production of telomeres, shows increased activity exclusively in tumors known to be malignant.[74,75] Similarly, antibody-based approaches that detect proliferating cells are being used increasingly to describe the malignant phenotype in tumors. One such antibody, MIP-1, selectively recognizes cells engaged in the cell cycle (i.e. scheduled to undergo mitosis, but not necessarily in the process of mitosis). Its predictability was explored in a survey of pheochromocytomas in which malignancy was confirmed by the existence of metastases. A positive MIB-1 labeling index (defined as >3% of tumor cells staining positive for MIB-1 vs the total number of cells counted) showed a specificity of 100% (benign tumors stained negative) and sensitivity of 50% (half of the malignant tumors stained positive).[76] Although sensitivity was poor, the ability to define benign disease accurately in this manner would be clinically reassuring.

Therapy

The historic importance of pheochromocytomas with respect to surgery is not the technical nature of their excision but the associated anesthetic risks. These relate to the potential for drastic changes in the excretion of catecholamines upon manipulation and subsequent removal of the tumor. The challenges revolve around stabilization of blood pressure intraoperatively and the prevention of potential cardiovascular collapse at the time of tumor removal or ligation of the veins delivering catecholamines to the systemic circulation. In

infants, particularly in the preoperative state, these risks are a great concern. In view of the high specificity and reduced invasiveness of modern serologic and radionuclide diagnostic methodologies, risk factors are reduced. Prevention of problems in the treatment of pheochromocytoma is considered one of the primary goals. As in adults, the mainstay of preoperative therapy includes blockade of α-adrenergic receptors (phenoxybenzamine) accompanied by adequate systemic volume repletion once the vasoconstrictive and volume-contracted state has been overcome. Cardiac β-blockade (propranolol) in every case to prevent reflex tachyarrhythmias remains controversial but should at least be considered in selected cases. Clearly, preoperative pharmacologic management of affected children should be undertaken in collaboration with the pediatric endocrinologist and anesthesiologist. If adequate blockade and volume replacement are achieved preoperatively, manipulation of the tumor is usually not accompanied by large variations in blood pressure and large additional volume requirements are usually not found necessary upon tumor removal.

Perianesthetic risks and outcomes of surgical resection have been recently outlined and still rely mainly on premedication and β-adrenergic blockade.[77] In this paper, the authors outline the methodologies of perioperative adrenal modulation, and confirm the absence of mortality, myocardial infarctions, or cerebrovascular events in a large series of patients (n = 41). They do confirm, however, a substantial morbidity, with 41 patients noting substantial intraoperative events, most commonly hypertension, or other intraoperative hemodynamic lability.

Open surgical excision by the flank or posterior lumbotomy approach has been the classic means of treatment. However, Rutherford et al[78] have published an excellent review of the laparoscopic experience of excision of these tumors. Laparoscopic removal is now the standard of care, although the limited operating space may be challenging in smaller children. Hwang et al[79] at the National Cancer Institute have confirmed the safety of this approach in children. They noted that patients treated laparoscopically have a significant reduction in recovery time as well as a low complication rate. It may well be that this will become the most widely accepted method of surgical excision.

Sacrococcygeal teratoma

Sacrococcygeal teratoma (SCT) is the most common neoplasm in the newborn, and one of the first tumors successfully excised surgically.[80] Virchow coined the term 'teratoma', referring to a coccygeal growth with diverse anatomic characteristics. The tumors originate from all three embryologic tissues: ectoderm, mesoderm, and endoderm. Although they have provoked great interest because of their occurrence early in life and their dramatic appearance at birth, they have achieved even more current interest because of the facility and frequency with which they can be diagnosed by antenatal ultrasonography.[81,82] Antenatal diagnosis is now the rule, with diagnosis, definition of intrauterine risk factors and, in some limited cases, intrauterine treatment being feasible.[83–85] The appearance and character of the tumors are highly variable since they may be internal or external. SCTs have no known etiology. They are usually benign, but may undergo malignant degeneration.

Pathology

A teratoma is a neoplasm composed of multiple tissues that are foreign to the area in which it arises. Teratomas are grouped into those benign lesions with mature tissue (70%), those having malignant anaplastic elements (20%), and a third, embryonic group (10%) that may contain histologically immature-appearing benign tissue that does not progress to mature organ formation.[86] This latter group carries a generally favorable prognosis following total excision. In the benign varieties, elements such as skin, teeth, central nervous system (CNS) tissue, cartilage, bone, and respiratory and alimentary mucosa may be seen.

Infants diagnosed with SCT at >1 year of age as well as older children are more likely to have malignant elements. To detect these elements, the pathologist must undertake an extensive search through all of the varied elements within the tumor. The term 'yolk sac' or endodermal sinus tumor is the name appropriately used for the malignant elements in such tumors. These tissues represent a separate element of the teratomatous cell line. Elevated serum levels of α-fetoprotein may be seen in these cases.

Clinical features and presentation

The traditional mode of presentation of these tumors has been discovery at birth. In most developed countries where antenatal sonography is now either mandatory or prevalent, they are discovered by antenatal sonography. A review[87] of antenatally diagnosed SCTs demonstrated a high incidence of in-utero mortality (19%) coupled with a perinatal mortality of 14%. The hydrops causing this in-utero mortality

may now be predicted by ultrasound[85] and MRI.[83] They may also be treated.[84] The incidence of premature labor in this series was 50%. Thus, although the pathology of SCT is often benign, the overall outcome is associated with considerable morbidity and mortality. Those clinical features in the antenatal state that correlated with a poorer prognosis included polyhydramnios (an early sign of fetal distress and predictor of placental megaly-hydrops fetalis), tumor hypervascularity, or the presence of a solid tumor (a risk factor for both malignancy and vascular steal syndrome), large tumor size at delivery (>10 cm in its greatest dimension), and a fast rate of tumor growth relative to cranial growth.

A solid tumor is the most ominous predictor of poor outcome. A fetus with a solid tumor has a mortality rate of 66% compared with a mortality of 11% for cystic or mixed tumors. Thus, mothers carrying a fetal diagnosis of SCT at the time of clinical obstetric presentation are definitely at risk for prenatal and perinatal complications. The presence of polyhydramnios appears to be a relative predictor or warning sign of premature labor.

There is a 5–25% association with other congenital anomalies in infants with benign SCT. Seventy-five percent of the infants are female, harboring primarily benign tumors.[71] The sex distribution is more evenly distributed between males and females in those whose tumors develop malignant degeneration.

Classification

The classification of SCT was proposed in 1974 by Altman and comprises: type 1, totally external; type 2, primarily external with internal component; type 3, almost completely internal; and type 4, totally internal[81] (Figure 77.11).

Today, since most SCTs may well be diagnosed in the antenatal state following obstetric ultrasonography, an improved prognosis may be anticipated following delivery by cesarean section. The latter is advised as an initial attempt to decrease perinatal mortality and morbidity. The major early cause for morbidity relates to tumor rupture, for which cesarean section is the best prophylaxis. In Altman's classification, large tumors were defined as being >10 cm, and these appear to be associated with greater morbidity.

When not diagnosed prior to birth, external tumors are found at delivery. Internal tumors may present as an abdominal mass, with the diagnosis of SCT noted by neonatal ultrasonography. Prior to the widespread use of prenatal ultrasound, some authors[88] had proposed that all newborns should have a rectal examination to exclude internal SCT, but acknowledged that the rarity of the tumor would result in positive identification in only 1 out of 400 000 babies.

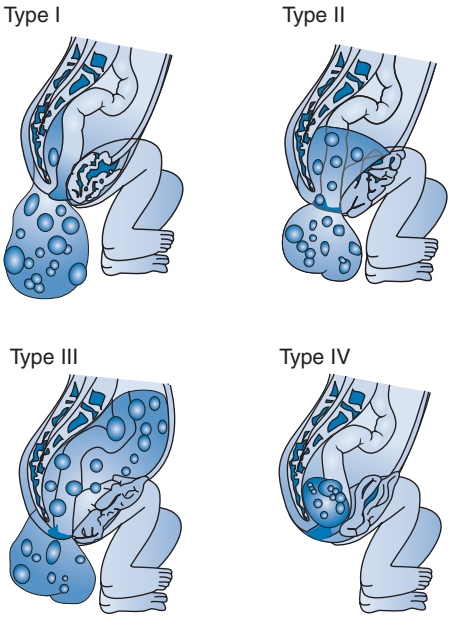

Figure 77.11 Classification of sacrococcygeal teratomas. Type 1: tumors are predominantly external (sacrococcygeal) with only a minimal presacral component. Type 2: tumors present externally but with a significant intrapelvic extension. Type 3: tumors are apparent externally but the predominant mass is pelvic and extends into the abdomen. Type 4: tumors are presacral with no external presentation. (Adapted from (Altman et al,[81] with permission.)

Laboratory

Tumors that undergo malignant degeneration may produce α-fetoprotein and/or β-human chorionic gonadotropin (β-hCG). These proteins are indicators of malignant degeneration in the dermal sinus or choriocarcinomatous components of the tumor.[80,89]

Imaging

Imaging studies for complete assessment include CT and MRI. Radiographic detection of calcification does not distinguish between benign and malignant tumors (Figures 77.12 and 77.13).

Treatment

With the increasing availability of antenatal diagnosis, the question of antenatal intervention has had a logical appeal. Other forms of intrauterine therapy, such

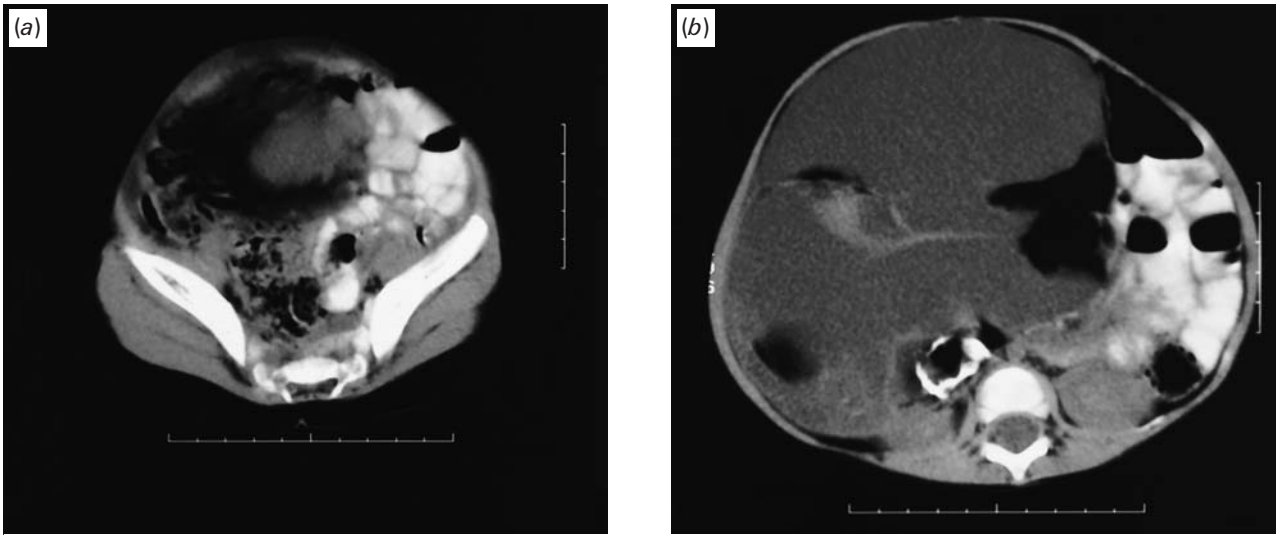

Figure 77.12 Computed tomographic images of cystic teratoma in a 6-month-old child, arising from the pelvis (*a*) and filling the abdomen (*b*).

as intrauterine transfusion and decompression of a dilated urinary tract, have been successful as early as 16 weeks' gestational age. It has been speculated that ligating the blood supply to the tumor prenatally may be effective in decreasing its size and/or controlling the hyperdynamic state in the perinatal period.[90,91] The Children's Hospital of Philadelphia has reported success in antenatal debulking in four fetuses out of 30 presenting in the period 1995–2003. Although one fetus died and the other three experienced significant morbidity, the authors consider the intervention potentially lifesaving in view of the higher mortality (16/30) of the overall group.[84]

Postnatal therapy of SCT is primarily surgical. Devascularization of the tumor may be of benefit; however, this is best applied as the first intraoperative component of surgical removal.[90,91] Complete surgical excision should be the rule, with en bloc removal of the involved portion of the coccyx. A laparoscopic approach may help with both control of the blood supply in infants or in dissection of the internal extensions of the tumor.[92] Burdis and coworkers at the Children's Hospital of Philadelphia have used cardiopulmonary bypass to facilitate removal of large tumors.[93]

The three clinical groups of presentations comprise:

- antenatal detection
- those that appear at birth or in the neonatal period with large, benign tumors
- those that appear later (>1 year of age), which are often smaller, fixed, and malignant.

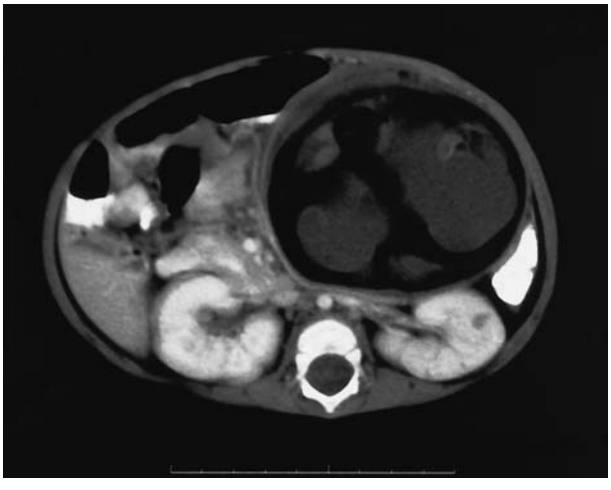

Figure 77.13 Computed tomographic image of a more solid teratoma filling the central abdomen in a 6-month-old child.

In the first two groups, total removal is the rule and is best achieved by a midline sacral or chevron incision. The coccyx should be removed in the process of excising the tumor. With the retroperitoneal extension of the teratoma, urinary, internal genital, and gastrointestinal organs may be displaced. They can usually be dissected free, with minimal injury to the viscera, and good access to the vascular supply of the tumor is usually afforded by this retroperitoneal approach. However, in more extensive cases, anterior abdominal exploration may be warranted. A generous surgical exposure to obtain control of the presacral vessels is recommended. Avulsion of the vessels is a

hazard to be avoided. In these instances, laparoscopic approaches prelaparotomy may be of benefit. In some rare instances, SCT may involve the dura or extend to the spine. This potential extension can be defined by meticulous preoperative imaging.[94–96] An inadvertent entry into the dura may result in a cerebrospinal fluid leak, which is associated with a higher morbidity. Modern imaging techniques, particularly MRI, will allow a clearer definition of these potential extensions to the CNS.

The third group represents those children in whom tumors present at an age >1 year. These tumors are generally symptomatic, fixed, and firm. Diagnosis is established by ultrasound and/or physical examination and confirmed by CT or MRI. These tumors are often of a malignant variety and serum α-fetoprotein is a sensitive marker. The appropriate surgical approach is initially directed at biopsy, followed by either multiagent chemotherapy or radiotherapy, in an attempt to decrease the size of the tumor, followed by surgical removal.

Results of therapy

Antenatal therapy may be advisable in a limited number of select fetuses, especially those at risk from high-output heart failure.[83–85] In postnatal excisions, those undertaken in infancy for both external and internal SCT are remarkably successful in achieving complete removal of tumors with relatively little long-term morbidity.[97] Incontinence is rare.[71] However, in those cases where high sacrococcygeal extension is present necessitating transabdominopelvic excision, long-term fecal soiling and incontinence may be more prevalent. These sequelae may be related to more direct injury of skeletal muscular components or to some more occult neurogenic impairment of the viscera.[98] These sequelae may also be seen in the newborns after the excision of large, benign tumors.

Malignant SCT is rare in children under 6 months of age but, beyond that, the incidence rises sharply.[99] Malignant tumors may invade adjacent tissues or may recur in up to 40% of cases. Chemotherapeutic regimes, established in the 1990s, have added considerably to the improved outcomes.[100,101]

Long-term follow-up

An evaluation of long-term follow-up in children with SCT showed that mature teratomas may have a recurrence rate of up to 11%. Further treatment with surgical excision and combined chemotherapy resulted in an 85% cure rate.[102] On long-term follow-up, a 3% recurrence rate was noted for immature teratomas. They were detected by a rising α-fetoprotein level 6 months after the initial procedure. These responded well to local excision. Endodermal sinus tumors detected and treated initially with surgical excisions represented only 9% of the tumors presenting at birth, whereas they represented 27% of the patients presenting at an older age. With long-term follow-up, 89% are still alive in spite of the higher recurrence rate.

Adrenal carcinoma

Adrenal carcinoma represents fewer than 0.0001% of neoplastic tumors in children. The most common presentation is abnormal virilization, occurring in two-thirds.[103] Symptoms consistent with Cushing's syndrome account for most of the remainder. Individual case reports have reported occasional aldosterone-secreting tumors. Given the widespread availability of ultrasound imaging technology, the most common presentation currently is that of an incidental finding on an abdominal ultrasound.

Adrenocortical tumors may also be a component of more global genetic malformations. These include children with congenital adrenal hyperplasia, multiple endocrine syndromes (MEN 1), and Beckwith–Wiedemann syndrome.

Clinical presentation

Virilizing adrenal tumors

Of the functioning adrenal cortical tumors, virilizing forms account for two-thirds, usually occurring in children >2 years. The tumors produce dehydroepiandrosterone (DHEA), a weak androgen but one that is converted to Δ^4-androstenedione and testosterone, which are more potent virilizing hormones. Boys with such tumors present with signs of precocious puberty. Girls respond with an increase in clitoral size, similar to that seen with congenital adrenal hyperplasia (Figure 77.14). Pubic and axillary hair may be seen in children of either gender.

Other causes of premature virilization in boys include interstitial cell tumors of the testis or as a delayed manifestation of congenital adrenal hyperplasia. Clinical evaluation may give some clues towards distinguishing the underlying etiology. Unilateral or asymmetric testicular enlargement suggests a Leydig cell tumor. In patients with centrally stimulated precocious puberty, testicular enlargement is bilateral.

Figure 77.14 Virilizing adrenal carcinoma in a 5-year-old girl. Note clitoral hypertrophy and pubic hair. There is no posterior labial fusion, as would be seen in congenital adrenal hyperplasia.

With virilizing adrenal tumors, the testes are usually small.

The differential diagnosis in female children includes ovarian arrhenoblastoma and other rare tumors of the adrenal cortex.

Cushing's syndrome

Approximately one-third of children with adrenocortical tumors have the stigmata of Cushing's syndrome. Carcinoma may be responsible in up to one-half, with the others having bilateral adrenal hyperplasia. A benign adenoma may rarely be seen. The clinical appearance is in response to the excessive production of cortisol. This leads to protein catabolism, increased gluconeogenesis, and the typical obesity associated with cortisol excess. The moon facies and truncal obesity (Figure 77.15) of Cushing's disease are generally obvious when they are present in infants.

The differential diagnosis in patients exhibiting excess adrenocortical activity includes adrenal adenomas and iatrogenic administration of steroids. This latter iatrogenic excess is commonly seen in children receiving transplanted organs.

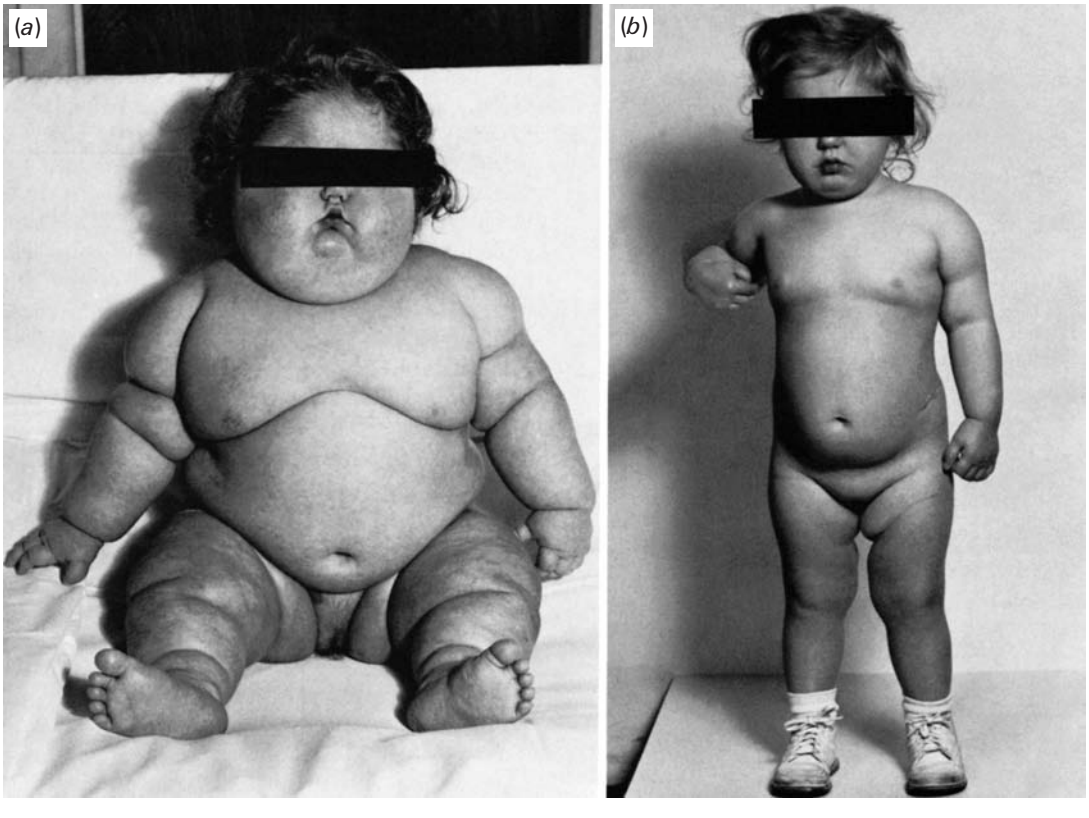

Figure 77.15 (*a*) Striking features of cortisol excess in a 17-month-old girl with adrenocortical carcinoma. In addition, pubic hair and mild enlargement of the clitoris were present. (*b*) At 10 months after removal of the adrenocortical carcinoma, there was complete regression of the signs of Cushing's syndrome.

Feminizing adrenal tumors

Feminizing adrenal tumors are rare. They occur more frequently in males, and in these cases the more commonly seen primary gynecomastia must be excluded.

Diagnostic evaluation

The critical diagnostic feature is the biochemical demonstration of adrenal hyperfunction. Urinary steroids typically show a markedly elevated 17-ketosteroid level. The free cortisol, DHA, and 17-hydroxysteroid levels may also be elevated.[104] Radioimmune assays of serum hormonal levels usually show elevation of DHEA, Δ^4-androstenedione, testosterone, and cortisol.[105] Serum estrogen levels are elevated in the rare feminizing cases.[106] Occasionally, an elevated serum aldosterone level can be demonstrated in cases of adrenocortical carcinoma.[107]

In Cushing's syndrome caused by adrenocortical carcinoma, the plasma cortisol level and urinary corticosteroids are markedly elevated above the levels typically seen with adrenal hyperplasia or an adrenal adenoma. A significant elevation in 17-ketosteroids, pregnanetriol, and estrogens may suggest carcinoma. The adrenocorticotropic hormone (ACTH) stimulation test produces no change in adrenocortical carcinomas, whereas those patients with adrenal hyperplasia show an exaggerated normal response. In exogenous obesity, which occasionally may enter the differential diagnosis, the ACTH test result is normal. When benign adenomas are present, the ACTH test exhibits a subnormal response. Metyrapone blocks 17β-hydroxylation in the adrenal cortex and leads to a fall in cortisol level with an increase in endogenous ACTH. Thus, a test with metyrapone produces results similar to those produced by the ACTH test. The diurnal variation usually seen in normal cortisol levels is absent with both tumors and adrenal hyperplasia. Dexamethasone blocks ACTH release in normal patients. The dexamethasone suppression test is useful to separate adrenal hyperplasia from tumors in that a large dose (8 mg) typically suppresses hyperplasia but not a tumor[108] (Table 77.5).

Modern diagnostic imaging has led to the greatest advances over the past decade (see section on imaging techniques under Neuroblastoma.) In addition to the ultrasound findings, MRI scanning has led to tremendous advances in the ability to distinguish adrenal carcinoma from benign adenomas.[109,110]

Treatment

Treatment of adrenal cortical carcinoma is surgical. In children, open surgical removal may be accomplished by large, transverse abdominal incisions or, in some instances, by extended flank incisions. Laparoscopic removal is now widely used in adults and is improving in children.[79] The advances in imaging allow more limited surgical approaches than may have been previously encountered. Tumor diameter of >5 cm is a reasonable predictor of malignancy, whereas small adenomas may be approached in a more limited manner. Preoperative care must recognize the need for corticosteroid replacement in cases where corticoid excess is anticipated.

The prognosis for adrenal carcinoma is poor. Surgery is the primary mode of therapy and chemotherapy has not been effective in controlling widespread disease.

Table 77.5 Test results with various adrenocortical lesions

Condition	Plasma cortisols		Dexamethasone test[a]			
	Concentration	Diurnal rhythm	Low-dose suppression	High-dose suppression	Metyrapone test response	Plasma ACTH
Normal	Normal	Yes	Yes	Yes	Yes	Normal
Cushing's disease	High	No	No	Yes	Yes	Increases
Tumor	High	No	No	No	No	Decrease
Non-ACTH-dependent hyperplasia	High	No	No	No	No	Decrease
Ectopic ACTH syndrome	High	No	No	No	No	Increase

[a]Low dose = 0.22 mg/10 kg for 2 days; high dose = 0.84 mg/10 kg for 3 days.
ACTH = adrenocorticotropic hormone.

Lymphangiomas

Lymphangiomas are benign tumors comprising a mass of anastomosing lymphatic channels. These are rare and most commonly affect the extremities. Most are congenital and may not become evident until a few years of age. When in the retroperitoneum, they are found by the evaluation of abdominal pain, which may be caused by the onset of spontaneous hemorrhage into the mass. However, they may extend through the inguinal canal and present with the misdiagnosis of hernia. Diagnosis is made on CT, at which time the low-density characteristic of lymphatic tissue is noted.

Surgical excision of the majority of the wall of the tumor is ideal, but may not be technically possible without causing significant damage to adjacent organs. Large cysts may be drained into the peritoneal cavity.

Neurofibroma

Patients with neurofibromatosis (von Recklinghausen's disease) may present with abdominal neurofibromas similar to but as a more benign variant of ganglioneuromas. As outlined in the previous section on benign ganglioneuromas, partial excision may be an appropriate surgical treatment.

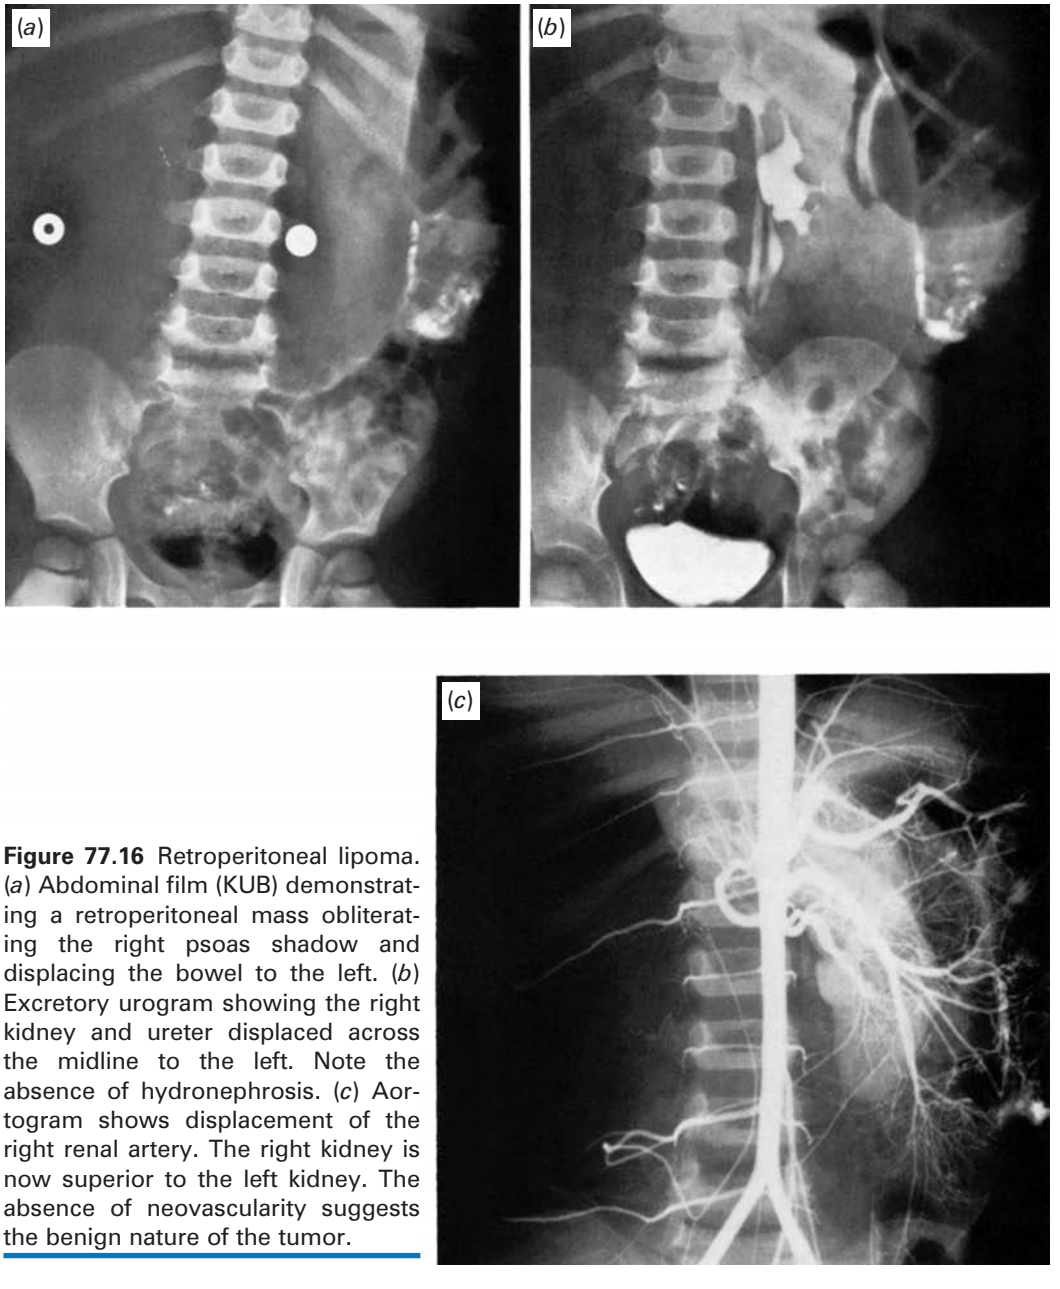

Figure 77.16 Retroperitoneal lipoma. (*a*) Abdominal film (KUB) demonstrating a retroperitoneal mass obliterating the right psoas shadow and displacing the bowel to the left. (*b*) Excretory urogram showing the right kidney and ureter displaced across the midline to the left. Note the absence of hydronephrosis. (*c*) Aortogram shows displacement of the right renal artery. The right kidney is now superior to the left kidney. The absence of neovascularity suggests the benign nature of the tumor.

Lipoma

Retroperitoneal lipomas are usually benign, presenting as an abdominal mass in infants and young children (Figure 77.16). CT defines the characteristically low-density lesions. These are generally benign and well encapsulated. Local excision is the treatment of choice.

Other malignant retroperitoneal tumors

Hodgkin's and non-Hodgkin's lymphomas may involve intra-abdominal viscera including the urinary and gastrointestinal tracts. Lateral deviation of the ureters is the most common genitourinary feature; however, ureteral obstruction may be the primary presenting symptom. Ureteral catheterization may become necessary in advance of chemotherapy.

Liposarcoma

Liposarcoma is rare in children, being seen more often in the teenage years leading into young adulthood. If it is identified early, surgical excision may result in complete cure.

Fibrosarcoma

Fibrosarcoma may be difficult to distinguish from neurofibroma. These lesions also occur primarily in the extremities, although retroperitoneal sites may be seen.

Introduction

The genitourinary system is exposed to a variety of possible injuries from the time the fetus develops. Individuals may suffer from congenital disorders, cancer, trauma, infection, inflammation, iatrogenic injuries, or other conditions that may lead to genitourinary organ damage or loss and necessitate eventual reconstruction. Whenever there is a lack of native urologic tissue, reconstruction may be performed with native non-urologic tissues (skin, gastrointestinal segments, or mucosa from multiple body sites), homologous tissues (cadaver fascia, cadaver or donor kidney), heterologous tissues (bovine collagen), or artificial materials (silicone, polyurethane, Teflon). The tissues used for reconstruction may lead to complications because of their inherently different functional parameters. In most cases, the replacement of lost or deficient tissues with functionally equivalent tissues would improve the outcome for these patients. This goal may be attainable with the use of tissue engineering techniques.

Tissue engineering: strategies for tissue reconstitution

Tissue engineering follows the principles of cell transplantation, materials science, and engineering toward the development of biologic substitutes that can restore and maintain normal function. Tissue engineering may involve matrices alone, wherein the body's natural ability to regenerate is used to orient or direct new tissue growth, or it may use matrices with cells. Inert biomaterials, without cells, can regenerate tissue when used for defects of up to 1 cm in diameter.

When cells are used for tissue engineering, donor tissue is dissociated into individual cells, which are implanted directly into the host or expanded in culture, attached to a support matrix, and reimplanted after expansion. The implanted tissue can be heterologous, allogeneic, or autologous. Ideally, this approach allows lost tissue function to be restored or replaced in toto and with limited complications.[1–18]

Biomaterials for genitourinary tissue engineering

Biomaterials in genitourinary tissue engineering function as an artificial extracellular matrix (ECM) and elicit biologic and mechanical functions of native ECM found in tissues in the body. Biomaterials facilitate the localization and delivery of cells and/or bioactive factors (e.g. cell adhesion peptides, growth factors) to desired sites in the body, define a three-dimensional space for the formation of new tissues with appropriate structure, and guide the development of new tissues with appropriate function.[19] Direct injection of cell suspensions without biomaterial matrices has been used in some cases,[20,21] but it is difficult to control the localization of transplanted cells.

Types of biomaterials

The ideal biomaterial should be biocompatible, promote cellular interaction and tissue development, and possess proper mechanical and physical properties. Generally, three classes of biomaterials have been used for engineering of genitourinary tissues:

- naturally derived materials such as collagen and alginate
- acellular tissue matrices such as bladder submucosa and small intestinal submucosa (SIS)
- synthetic polymers such as polyglycolic acid (PGA), polylactic acid (PLA), and poly(lactic-co-glycolic acid) (PLGA).

Naturally derived materials and acellular tissue matrices have the potential advantage of biologic recognition. Synthetic polymers can be produced reproducibly on a large scale with controlled properties of strength, degradation rate, and microstructure.

Vascularization

One of the restrictions of the engineering of tissues is that cells cannot be implanted in volumes exceeding 3 mm^3 because of the limitations of nutrition and gas exchange.[22] To achieve the goals of engineering large complex tissues, and possibly internal organs, vascularization of the regenerating cells is essential.

Three approaches have been used for vascularization of bioengineered tissue:

- incorporation of angiogenic factors in the bioengineered tissue
- seeding ECM with other cell types in the bioengineered tissue
- prevascularization of the matrix prior to cell seeding.

Angiogenic growth factors may be incorporated into the bioengineered tissue prior to implantation, in order to attract host capillaries and to enhance neovascularization of the implanted tissue. There are many obstacles to overcome before large entire tissue-engineered solid organs are produced. Current research in the field of angiogenesis research may provide important knowledge and essential materials to accomplish this goal.

Tissue engineering of urologic structures

Urethra

Various strategies have been proposed over the years for the regeneration of urethral tissue. Woven meshes of PGA (Dexon), without cells, have been used to reconstruct urethras in dogs.[23,24] PGA has been used as a cell transplantation vehicle to engineer tubular urothelium in vivo.[1] SIS without cells was used as an onlay patch graft for urethroplasty in rabbits.[25] A homologous free graft of acellular urethral matrix was also used in a rabbit model.[26]

Bladder-derived acellular collagen matrix has proven to be a suitable graft for repair of urethral defects in rabbits. The neourethras created in the rabbit model demonstrated a normal urothelial luminal lining and organized muscle bundles.[27] These results were confirmed clinically in a series of patients with a history of failed hypospadias reconstruction wherein the urethral defects were repaired with human bladder acellular collagen matrices (Figure 78.1).[28] One of the advantages of this material over non-genital tissue grafts used for urethroplasty is that it is 'off the shelf.' This

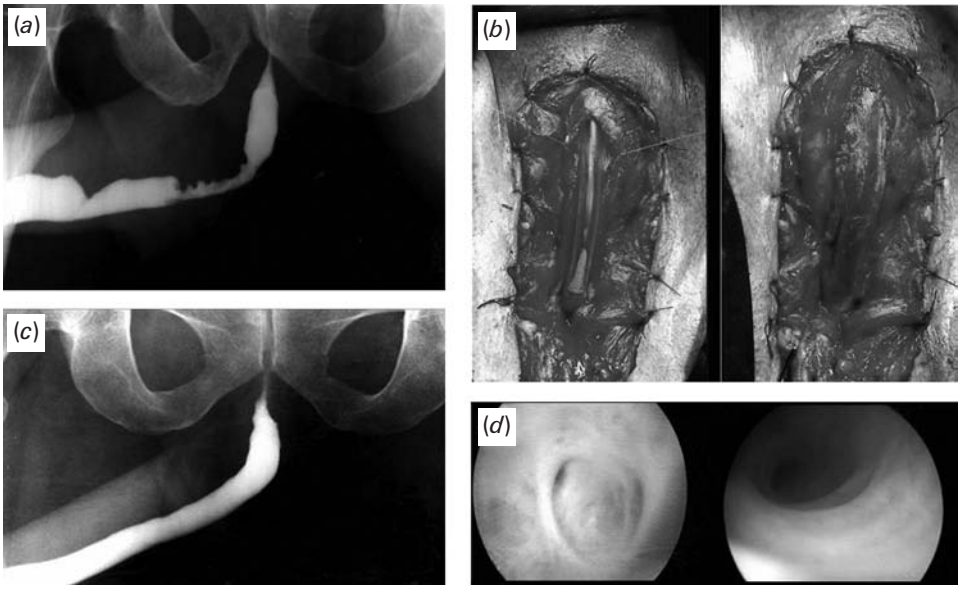

Figure 78.1 Tissue engineering of the urethra using a collagen matrix. (*a*) Representative case of a patient with a bulbar stricture. (*b*) Urethral repair. Strictured tissue is excised, preserving the urethral plate on the left side, and matrix is anastomosed to the urethral plate in an onlay fashion on the right. (*c*) Urethrogram 6 months after repair. (*d*) Cystoscopic view of urethra before surgery on the left side and 4 months after repair on the right side.

eliminates the necessity of additional surgical procedures for graft harvesting, which may decrease operative time, as well as the potential morbidity resulting from the harvest procedure.

The above techniques, using non-seeded acellular matrices, were applied experimentally and clinically in a successful manner for onlay urethral repairs. However, when tubularized urethral repairs were attempted experimentally, adequate urethral tissue regeneration was not achieved, and complications ensued, such as graft contracture and stricture formation.[29] Seeded tubularized collagen matrices have performed better in animal studies. In a rabbit model, entire urethral segments were resected and urethroplasties were performed with tubularized collagen matrices either seeded with cells, or without cells. The tubularized collagen matrices seeded with autologous cells formed new tissue that was histologically similar to native urethra. The tubularized collagen matrices without cells led to poor tissue development, fibrosis, and stricture formation, findings that were recently confirmed clinically.[30]

Bladder

Currently, gastrointestinal segments are commonly used as tissues for bladder replacement or repair. However, gastrointestinal tissues are designed to absorb specific solutes, and when they come in contact with the urinary tract multiple complications may ensue, such as infection, metabolic disturbances, urolithiasis, perforation, increased mucus production, and malignancy.[31–33] Because of the problems encountered with the use of gastrointestinal segments, numerous investigators have attempted alternative reconstructive procedures for bladder replacement or repair such as the use of tissue expansion, seromuscular grafts, matrices for tissue regeneration, and tissue engineering with cell transplantation. A clinical experience involving engineered bladder tissue for cystoplasty reconstruction was commenced in 1999. A small pilot series of 7 patients was reported, which used a collagen scaffold seeded with cells either with or without omentum coverage, or a combined PGA-collagen scaffold seeded with cells and omental coverage. The patients reconstructed with the engineered bladder tissue created with the PGA-collagen cell-seeded scaffolds showed increased compliance, decreased end-filling pressures, increased capacities and longer dry periods.[33]

Tissue expansion for bladder augmentation

A system of progressive dilation for ureters and bladders has been proposed as a method of bladder augmentation but has not yet been attempted clinically.[34,35] Augmentation cystoplasty performed with the dilated ureteral segment in animals has resulted in an increased bladder capacity ranging from 190% to 380%.[34] A system for the progressive expansion of native bladder tissue has also been used for augmenting bladder volumes in animals. Within 30 days after progressive dilation, the neoreservoir volume was expanded at least 10-fold. Urodynamic studies showed normal compliance in all animals, and microscopic examination of the expanded neoreservoir tissue showed a normal histology. A series of immunocytochemical studies demonstrated that the dilated bladder tissue maintained normal phenotypic characteristics.[35]

Seromuscular grafts and de-epithelialized bowel segments

Seromuscular grafts and de-epithelialized bowel segments, either alone or over a native urothelium, have also been attempted.[36–42] Keeping the urothelium intact avoids the complications associated with use of bowel in continuity with the urinary tract.[37,38] An example of this strategy is the combination of the techniques of autoaugmentation with those of enterocystoplasty. An autoaugmentation is performed and, the diverticulum is covered with a demucosalized gastric or intestinal segment.[42]

Matrices for bladder regeneration

Non-seeded allogeneic acellular bladder matrices have served as scaffolds for the ingrowth of host bladder wall components. The matrices are prepared by mechanically and chemically removing all cellular components from bladder tissue.[14,43–45] The matrices serve as vehicles for partial bladder regeneration, and relevant antigenicity is not evident. For example, SIS, a biodegradable, acellular, xenogeneic collagen-based tissue–matrix graft, was first used in the early 1980s as an acellular matrix for tissue replacement in the vascular field. It has been shown to promote regeneration of a variety of host tissues, including blood vessels and ligaments.[46] Animal studies have shown that the non-seeded SIS matrix used for bladder augmentation is able to regenerate in vivo.[47,48]

In multiple studies using various materials as non-seeded grafts for cystoplasty, the urothelial layer was able to regenerate normally, but the muscle layer, although present, was not fully developed.[14,43,44,48] Often the grafts contracted to 60–70% of their origi-

nal sizes,[49] with little increase in bladder capacity or compliance.[50] Studies involving acellular matrices that may provide the necessary environment to promote cell migration, growth, and differentiation are being conducted. With continued bladder research in this area, these matrices may have a clinical role in bladder replacement in the future. Recently, bladder regeneration has been shown to be more reliable when the SIS was derived from the distal ileum.[47]

Bladder replacement using tissue engineering

Cell-seeded allogeneic acellular bladder matrices have been used for bladder augmentation in dogs. A group of experimental dogs underwent a trigone-sparing cystectomy and were randomly assigned to one of three groups: one group underwent closure of the trigone without a reconstructive procedure; another group underwent reconstruction with a non-seeded bladder-shaped biodegradable scaffold; and the third group underwent reconstruction using a bladder-shaped biodegradable scaffold that delivered seeded autologous urothelial cells and smooth muscle cells.[17]

The cystectomy-only and non-seeded controls maintained average capacities of 22% and 46% of preoperative values, respectively. An average bladder capacity of 95% of the original precystectomy volume was achieved in the cell-seeded tissue-engineered bladder replacements (Figure 78.2). The subtotal cystectomy reservoirs (Figure 78.2a) that were not reconstructed and the polymer-only reconstructed bladders (Figure 78.2b) showed a marked decrease in bladder compliance (10% and 42% of the preoperative value, respectively). The compliance of the cell-seeded tissue-engineered bladders (Figure 78.2c) showed no difference from preoperative values that were measured when the native bladder was present (106%). Histologically, the non-seeded scaffold bladders presented a pattern of normal urothelial cells, with a thickened fibrotic submucosa and a thin layer of muscle fibers. The retrieved tissue-engineered bladders showed a normal cellular organization, consisting of a trilayer of urothelium, submucosa, and muscle.[17] Preliminary clinical trials for the application of this technology have been performed and are currently under evaluation.

Genital tissues

Reconstruction of corporeal smooth muscle

One of the major components of the phallus is corporeal smooth muscle. The creation of autologous functional and structural corporeal tissue de novo would be beneficial. In order to look at the functional parameters of the engineered corpora, acellular corporeal collagen matrices were obtained from donor rabbit penis, and autologous corpus cavernosal smooth muscle and endothelial cells were harvested, expanded, and seeded

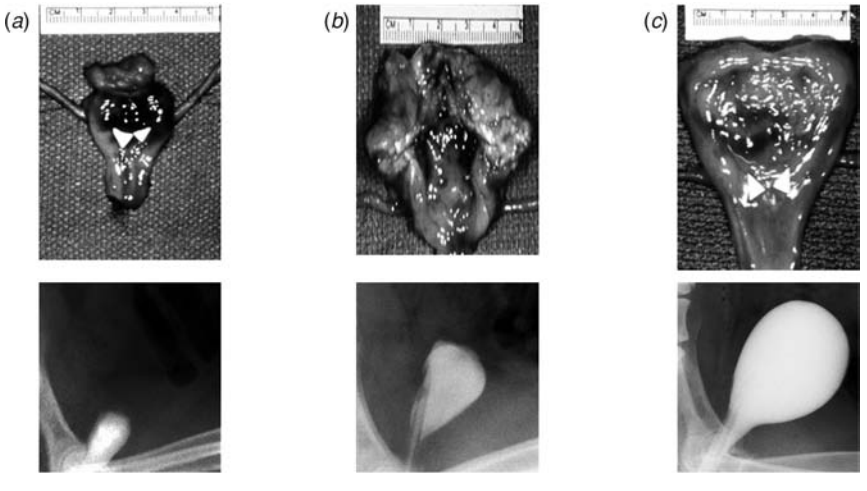

Figure 78.2 Gross specimens and cystograms at 11 months of the cystectomy-only (*a*), non-seeded (polymer implants only) controls (*b*) and cell-seeded tissue-engineered bladder replacements (*c*). The cystectomy-only bladder had a capacity of 22% of the preoperative value and a decrease in bladder compliance to 10% of the preoperative value. The non-seeded controls showed significant scarring, with a capacity of 46% of the preoperative value and a decrease in bladder compliance to 42% of the preoperative value. An average bladder capacity of 95% of the original precystectomy volume was achieved in the cell-seeded tissue-engineered bladder replacements and the compliance showed almost no difference from preoperative values that were measured when the native bladder was present (106%).

on the matrices. The entire rabbit corpora was removed and replaced with the engineered scaffolds. The experimental corporeal bodies demonstrated intact structural integrity by cavernosography and showed similar pressure by cavernosometry when compared with the normal controls. The control rabbits without cells failed to show normal erectile function throughout the study period. Mating activity in the animals with the engineered corpora appeared normal by 1 month after implantation. The presence of sperm was confirmed during mating, and was present in all the rabbits with the engineered corpora. The female rabbits mated with the animals implanted with engineered corpora conceived and delivered healthy pups. Animals implanted with the matrix alone were unable to demonstrate normal mating activity and failed to ejaculate into the vagina.[51]

Engineered penile prostheses

Although silicone is an accepted biomaterial for penile prostheses, biocompatibility is a concern.[52,53] The use of a natural prosthesis composed of autologous cells may be advantageous. In a recent study using an autologous system, the feasibility of applying the engineered cartilage rods in situ was investigated.[54] Autologous chondrocytes harvested from rabbit ear were grown and expanded in culture. The cells were seeded onto biodegradable PLA-coated PGA polymer rods and implanted into the corporeal spaces of rabbits. Examination at retrieval showed the presence of well-formed, milky-white cartilage structures within the corpora at 1 month. All polymers were fully degraded by 2 months. There was no evidence of erosion or infection in any of the implantation sites. Subsequent studies were performed to assess the long-term functionality of the cartilage penile rods in vivo. To date, the animals have done well and can copulate and impregnate their female partners without problems.

Female genital tissues

Congenital malformations of the uterus may have profound implications clinically. Patients with cloacal exstrophy and intersex disorders may not have sufficient uterine tissue present for future reproduction. We investigated the possibility of engineering functional uterine tissue using autologous cells.[55] Autologous rabbit uterine smooth muscle and epithelial cells were harvested, then grown and expanded in culture. These cells were seeded onto preconfigured uterine-shaped biodegradable polymer scaffolds, which were then used for subtotal uterine tissue replacement in the corresponding autologous animals. Upon retrieval 6 months after implantation, histologic, immunocytochemical, and Western blot analyses confirmed the presence of normal uterine tissue components. Biomechanical analyses and organ bath studies showed that the functional characteristics of these tissues were similar to those of normal uterine tissue. Breeding studies using these engineered uteri are currently being performed.

Similarly, several pathologic conditions, including congenital malformations and malignancy, can adversely affect normal vaginal development or anatomy. Vaginal reconstruction has traditionally been challenging, because of the paucity of available native tissue. Vaginal epithelial and smooth muscle cells of female rabbits were harvested, grown, and expanded in culture. These cells were seeded onto biodegradable polymer scaffolds, and the cell-seeded constructs were then implanted into nude mice for up to 6 weeks. Immunocytochemical, histologic, and Western blot analyses confirmed the presence of vaginal tissue phenotypes. Electrical field stimulation studies in the tissue-engineered constructs showed similar functional properties to those of normal vaginal tissue. When these constructs were used for autologous total vaginal replacement, patent vaginal structures were noted in the tissue-engineered specimens, whereas the non-cell-seeded structures were noted to be stenotic.[56]

Ureters

Ureteral non-seeded matrices have been used as a scaffold for the ingrowth of ureteral tissue in rats. On implantation, the acellular matrices promoted the regeneration of the ureteral wall components.[57] Ureteral replacement with polytetrafluoroethylene (Teflon) grafts was also attempted in dogs, but with poor functional results.[58] In a more recent study, non-seeded ureteral collagen acellular matrices were tubularized and used to replace 3 cm segments of canine ureters. The non-seeded acellular matrix tube was not able to successfully replace the segment of the ureter.[59]

Cell-seeded biodegradable polymer scaffolds have been used with more success to reconstruct ureteral tissues. In one study, urothelial and smooth muscle cells isolated from bladders and expanded in vitro were seeded onto PGA scaffolds with tubular configurations and implanted subcutaneously into athymic mice. After implantation, the urothelial cells proliferated to form a multilayered luminal lining of tubular structures, while the smooth muscle cells organized into multilayered structures surrounding

the urothelial cells. Abundant angiogenesis was evident. The degradation of the polymer scaffolds resulted in the eventual formation of natural urothelial tissues. This approach was expanded to replacement of ureters in dogs by transplantation of smooth muscle cells and urothelial cells on tubular polymer scaffolds.[60]

Formation of renal structures

The kidney is probably the most challenging organ in the genitourinary system to reconstruct by tissue engineering techniques because of its complex structure and function. Emerging concepts for a bioartificial kidney are currently being explored. Some investigators are pursuing the replacement of isolated kidney function parameters with the use of extracorporeal units, whereas others are aiming at the replacement of total renal function by tissue-engineered bioartificial structures.

Ex-vivo functioning renal units

Although dialysis is currently the most prevalent form of renal replacement therapy, the relatively high morbidity and mortality have spurred investigators to seek alternative solutions involving ex-vivo systems. In an attempt to assess the viability and physiologic functionality of a cell-seeded device to replace the filtration, transport, metabolic, and endocrinologic functions of the kidney in acutely uremic dogs, a combination of a synthetic hemofiltration device and a renal tubular cell therapy device containing porcine renal tubules in an extracorporeal perfusion circuit was introduced. It was shown that levels of potassium and blood urea nitrogen (BUN) were controlled during treatment with the device. The fractional reabsorption of sodium and water was possible. Active transport of potassium, bicarbonate, and glucose and a gradual ability to excrete ammonia was observed. These results showed the technologic feasibility of an extracorporeal assist device that is reinforced by the use of proximal tubular cells.[61]

Using similar techniques, the development of a tissue-engineered bioartificial kidney consisting of a conventional hemofiltration cartridge in series with a renal tubule assist device containing human renal proximal tubule cells was used in patients with acute renal failure (ARF) in the intensive care unit. The initial clinical experience with the bioartificial kidney and the renal tubule assist device suggests that renal tubule cell therapy may provide a dynamic and individualized treatment program as assessed by acute physiologic and biochemical indices.[62]

Creation of functional renal structures in vivo

Another approach towards the achievement of improved renal function involves the augmentation of renal tissue with kidney cell expansion in vitro and subsequent autologous transplantation. The feasibility of achieving renal cell growth, expansion, and in-vivo reconstitution with the use of tissue engineering techniques has been explored.

Most recently, an attempt was made to harness the reconstitution of renal epithelial cells for the generation of functional nephron units. Renal cells were harvested and expanded in culture. The cells were seeded onto a tubular device constructed from a polycarbonate membrane, connected at one end with a Silastic catheter that terminated into a reservoir. The device was implanted in athymic mice. Histologic examination of the implanted devices over time revealed extensive vascularization with formation of glomeruli and highly organized tubule-like structures. Immunocytochemical staining confirmed the renal phenotype. Yellow fluid was collected from inside the implant, and the fluid retrieved was consistent with the makeup of dilute urine in its creatinine and uric acid concentrations.[63] Further studies have been performed showing the formation of renal structures in cows using nuclear transfer techniques (Figure 78.3).[64] This technology will have to surmount significant challenges, including the expansion of this system to larger, three-dimensional structures.

Other applications of genitourinary tissue engineering

Fetal tissue engineering

The prenatal diagnosis of fetal abnormalities is now more prevalent and accurate. The natural consequence of the evolution in prenatal diagnosis is the use of intervention before birth to reverse potentially life-threatening processes.

There are several strategies that may be pursued to facilitate the future prenatal management of patients with urologic disease. Having a ready supply of urologic-associated tissue for surgical reconstruction at birth may be advantageous. Theoretically, once the diagnosis of the pathologic condition is confirmed prenatally, a small tissue biopsy could be obtained under ultrasound guidance. These biopsy materials could

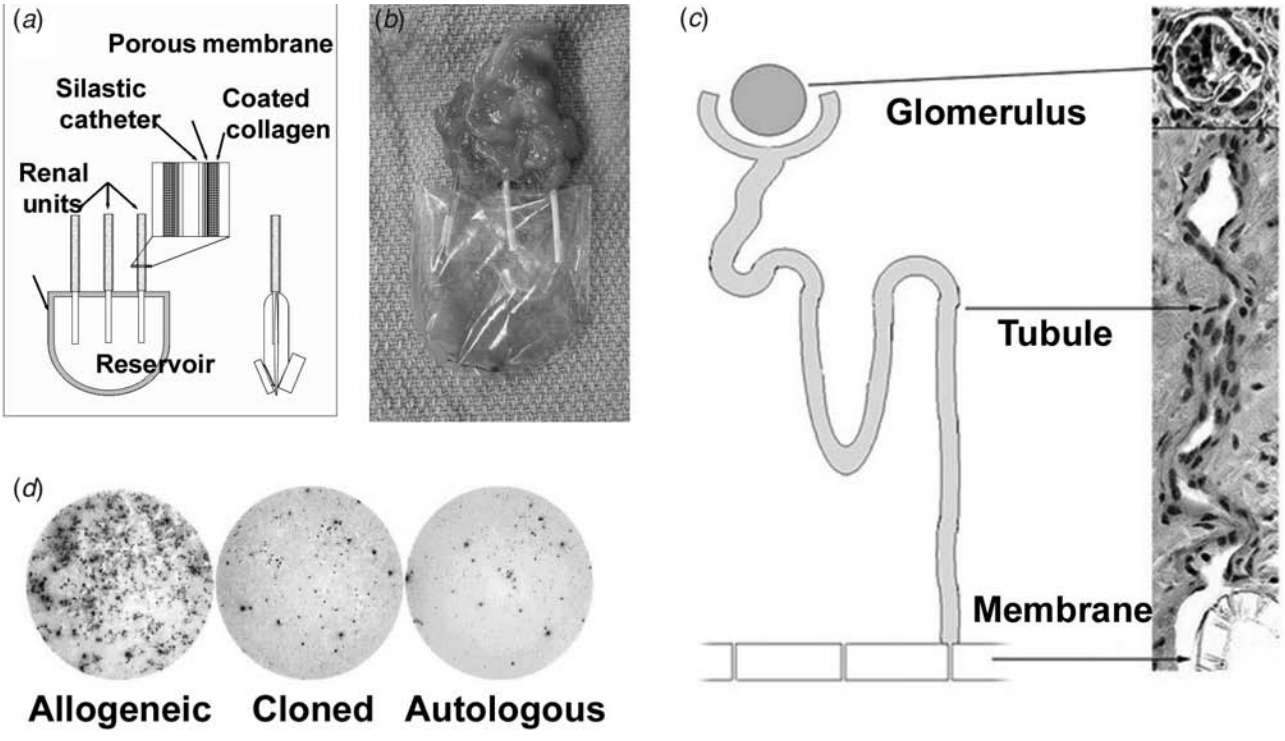

Figure 78.3 Combining therapeutic cloning and tissue engineering to produce kidney tissue. (*a*) Illustration of the tissue-engineered renal unit. (*b*) Renal unit seeded with cloned cells, 3 months after implantation, showing the accumulation of urine-like fluid. (*c*) There was a clear unidirectional continuity between the mature glomeruli, their tubules, and the polycarbonate membrane. (*d*) ELISPOT analyses of the frequencies of T cells that secrete interferon-γ (IFN-γ) after primary and secondary stimulation with allogeneic renal cells, cloned renal cells, or nuclear donor fibroblasts.

then be processed and the various cell types expanded in vitro. Using tissue engineering techniques, reconstituted structures in vitro could then be readily available at the time of birth for reconstruction.

Injectable therapies

Both urinary incontinence and vesicoureteral reflux (VUR) are common conditions affecting the genitourinary system for which injectable bulking agents can be used for treatment. The ideal substance for endoscopic treatment of VUR and incontinence should be injectable, non-antigenic, non-migratory, volume stable, and safe for human use. Animal studies have shown that chondrocytes can be easily harvested and combined with alginate in vitro; the suspension can be easily injected cystoscopically. The elastic cartilage tissue formed is able to correct VUR without any evidence of obstruction.[65] The first human application of cell-based tissue engineering technology for urologic applications occurred with the injection of chondrocytes for the correction of VUR in children and for urinary incontinence in adults (Figure 78.4).[66,67]

Using cell therapy techniques, autologous smooth muscle cells were explored for both urinary incontinence and VUR applications.[68] The potential use of injectable, cultured myoblasts for the treatment of stress urinary incontinence has also been investigated.[69,70] The use of injectable muscle precursor cells has also been investigated for use in the treatment of urinary incontinence due to irreversible urethral sphincter injury or maldevelopment.[71] A clinical trial involving the use of muscle-derived stem cells (MDSC) to treat stress urinary incontinence has also been performed with good results. Biopsies of skeletal muscle were obtained, and autologous myoblasts and fibroblasts were cultured. Under ultrasound guidance, myoblasts were injected into the rhabdosphincter, and fibroblasts mixed with collagen were injected into the submucosa. One year following injection, the thickness and function of the rhabdosphincter had significantly increased, and all patients were continent.[72] These are the first demonstrations of the replacement of both sphincter muscle tissue and its innervation by the injection of muscle precursor cells.

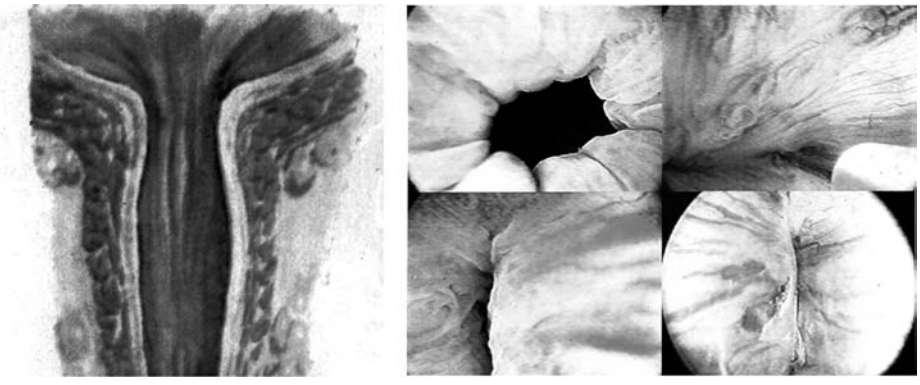

Figure 78.4 Chondrocytes are harvested and combined with alginate in vitro, and the suspension is injected cystoscopically as a bulking agent to treat urinary incontinence.

In addition, injectable muscle-based gene therapy and tissue engineering were combined to improve detrusor function in a bladder injury model, and may potentially be a novel treatment option for urinary incontinence.[73]

Patients with testicular dysfunction require androgen replacement for somatic development. Conventional treatment for testicular dysfunction consists of periodic intramuscular injections of chemically modified testosterone or, more recently, skin patch applications. However, long-term non-pulsatile testosterone therapy is not optimal and can cause multiple problems, including erythropoiesis and bone density changes.

A system was designed wherein Leydig cells were microencapsulated for controlled testosterone replacement. Purified Leydig cells were isolated and encapsulated in an alginate–poly-L-lysine solution. The encapsulated Leydig cells were injected into castrated animals, and serum testosterone was measured serially; the animals were able to maintain testosterone levels in the long term.[74] These studies suggest that microencapsulated Leydig cells may be able to replace or supplement testosterone in situations where anorchia or testicular failure is present.

Concerns in tissue engineering

An area of concern in the field of tissue engineering in the past was the source of cells for regeneration. The concept of creating engineered constructs involves initially obtaining cells for expansion from the diseased organ. A study recently showed that cultured neuropathic bladder smooth muscle cells possess and maintain different characteristics than normal smooth muscle cells in vitro, as demonstrated by growth assays, contractility and adherence tests in vitro.[75] However, when neuropathic smooth muscle cells were cultured in vitro, and seeded onto matrices and implanted in vivo, the tissue-engineered constructs showed the same properties as the tissues engineered with normal cells.[76] It is known that genetically normal progenitor cells, which are the reservoirs for new cell formation, are programmed to give rise to normal tissue, regardless of whether the niche resides in either normal or diseased tissues. The stem cell niche and its role in normal tissue regeneration remains a fertile area of ongoing investigation.

Stem cells for tissue engineering

Most current strategies for tissue engineering depend upon a sample of autologous cells from the diseased organ of the host. However, for many patients with extensive end-stage organ failure, a tissue biopsy may not yield enough normal cells for expansion and transplantation. In other instances, primary autologous human cells cannot be expanded from a particular organ, such as the pancreas. In these situations, pluripotent human embryonic stem cells are envisioned as a viable source of cells, as they can serve as an alternative source of cells from which the desired tissue can be derived.

Embryonic stem cells exhibit two remarkable properties: the ability to proliferate in an undifferentiated, but pluripotent state (self-renew), and the ability to differentiate into many specialized cell types.[77] They can be isolated by immunosurgery from the inner cell mass of the embryo during the blastocyst stage (5 days post-fertilization). These cells have demonstrated longevity in culture by maintaining their undifferentiated state for at least 80 passages when grown using current published protocols.[78]

Adult stem cells have the advantage of avoiding some of the ethical issues associated with embryonic

cells, and also they do not transdifferentiate spontaneously to a malignant phenotype. The use of adult stem cells is limited for clinical therapy due to the difficulties encountered with cell expansion to large quantities.

Fetal stem cells derived from amniotic fluid and placentas have been recently described and represent a novel source of stem cells. The cells express markers consistent with human embryonic stem cells, such as OCT4 and SSEA-4, but do not form teratomas, and do not spontaneously transdifferentiate to a malignant phenotype. The cells are multipotent and are able to differentiate into all three germ layers. In addition, the cells have a high replicative potential and could be stored for future self-use, without the risks of rejection, and without ethical concerns.[79]

Therapeutic cloning

Nuclear cloning, which has also been called nuclear transplantation and nuclear transfer, involves the introduction of a nucleus from a donor cell into an enucleated oocyte to generate an embryo with a genetic makeup identical to that of the donor. Two types of nuclear cloning – reproductive cloning and therapeutic cloning – have been described. Banned in most countries for human applications, reproductive cloning is used to generate an embryo that has the identical genetic material to its cell source. This embryo can then be implanted into the uterus of a female to give rise to an infant that is a clone of the donor. On the other hand, therapeutic cloning is used to generate early-stage embryos that are explanted in culture to produce embryonic stem cell lines whose genetic material is identical to that of its source. These autologous stem cells have the potential to become almost any type of cell in the adult body, and thus would be useful in tissue and organ replacement applications (Figure 78.5).[80] Some useful applications would be in the treatment of diseases, such as end-stage kidney disease, for which there is limited availability of immunocompatible tissue transplants.

Conclusions

Tissue engineering efforts are currently being undertaken for every type of tissue and organ within the urinary system. Most of the effort expended to engineer genitourinary tissues has occurred within the last decade. Tissue engineering techniques require a cell culture facility designed for human application. Personnel who have mastered the techniques of cell harvest, culture, and expansion as well as polymer design are essential for the successful application of this technology. Before these engineering techniques can be applied to humans, further studies need to be performed in many of the tissues described. Recent progress suggests that engineered urologic tissues and cell therapy may have clinical applicability.

ureteral calculi 416–17
uric acid 394
urologic anomalies, screening 23–5
fetal 23–4
nonlethal 24–5
uropathy, fetal, pathophysiology of 20–1
uterus
abnormalities *1144*
bicornuate 295, *295*

formation *1143*

VACTERL syndrome 295, *799*
prune belly syndrome and 1083
vagina
abnormalities *1144*
cysts 208
formation *1143*
hypoplasia of 295
vaginitis 172, 208–9
vaginosis, bacterial 209
varicocele 73, 1247–50, *1249*
definition and incidence 1282
etiology and pathophysiology 1282–4
postoperative hydrocele treatment after 1287
presentation and diagnosis 1284–5
recurrence 1287
repair techniques 1286–*7*
testicular histology *1248*
treatment 1285–6
vas deferens, ectopy of 1262
VATER syndrome *799*
VATER/VACTERL association 1162
vena cava, development 283, *284*
vesicoamniotic shunting, complications *21*
vesicomyectomy 892–5, *893*
vesicomyotomy 892–5, *893*
vesicostomy drainage *792*
vesicourachal diverticulum 1054, 1056
vesicoureteral reflux (VUR) 20, 37, 38, 67, 232, 271, 546–9
α-blocker therapy 668
antibiotic prophylaxis 665–*7*
anticholinergic therapy 668
biofeedback 669
bladder training 667
classification 132–3, *133*
constipation 668–9
demographic features 658–9
fetal 21
follow-up assessment 669–70
follow-up cystography 669–70
historical perspective 655
lower urinary tract function in 660–1
management 372
non-surgical management 663–70
prenatal detection 29–30
primary vs secondary 659
prophylaxis 145–6
reflux resolution 663–5
